BAZAR, Bazari, or Bazaard, a place designed for trade among the eastern nations, particularly the Persians, some of which are open at top, like the market places of Europe; others are covered with high vaulted ceilings, and adorned with domes to give light.

At Constantinople the old and new bazar are large square buildings, covered with domes, and sustained by arches and pilastres; the former chiefly for arms, harnesses, and the like; the latter for goldsmiths, jewellers, furriers, and all sorts of manufactures.

BAZAT, or Baza, in commerce, a long, fine, spun cotton, which comes from Jerusalem, whence it is called Jerusalem cotton.

BAZENDGES, the name of a vegetable substance used by the Turks, and other eastern nations, in the scarlet dyeing. They mix it for this purpose with cochineal and tartar, in the proportion of two parts of bazendges to one of cochineal.

BDELLIUM, a gum resin somewhat resembling myrrh in appearance, brought from the Levant. It is met with in single drops, of a very irregular size, some of which are as large as a hazle nut. Its colour is dusky, and its taste bitter.

There is much uncertainty concerning both the plant from which it proceeds, and the place of its production. The smell of this gum is fragrant, and its taste bitter and pungent. It readily burns, giving out smoke and a crackling noise. It is partly soluble in alcohol, and partly in water, or completely in diluted spirit. It was formerly used as a stimulating remedy, chiefly for external application, and is still retained in the Paris dispensatories.

BEACON, a public signal, to give warning against rocks, shelves, invasions, &c. It is made sometimes by putting pitch barrels upon a long pole, and fixing them up

on an eminence, so that they may be seen at a distance; for the barrels being fired, the flame in the night time, and the smoke in the day, give notice, and in a few hours may alarm the whole kingdom, upon an approaching invasion, &c.

BEACONAGE, a tax or farm paid for the use and maintenance of a beacon. The Trinity house is empowered to levy this tax, by act of parliament.

BEAD. The common black glass of which beads are made for necklaces, &c. is coloured with manganese only.

Bead, in architecture, a round moulding, commonly made upon the edge of a piece of stuff, in the Corinthian and Roman orders, cut or carved in short embossments, like beads in necklaces. Sometimes a plain bead is set on the edge of each fascia of an architrave, and sometimes likewise an astragal is thus cut. A bead is often placed on the lining board of a doorcase, and on the upper edges of skirting boards.

Bead *proof*, among distillers and venders of liquors, a fallacious mode of determining the strength of spirits, from the continuance of the bubbles, or beads, raised by shaking a small quantity of them in a phial.

Bead *roll*, among papists, a list of such persons for the rest of whose souls they are obliged to repeat a certain number of prayers, which they count by means of their beads.

BEAGLE. See Canis.

BEAK, the bill or nib of a bird. See Bill.

Beak, in architecture, the small fillet left on the head of a larmier, which forms a canal, and makes a kind of pendant.

Beak, or Beak head, of a ship, that part without a ship, before the forecastle, which is fastened to the stern, and is supported by the main knee.

BEAKED, in heraldry, a term used to express the beak or bill of a bird. When the beak and legs of a fowl are of a different tincture from the body, we say beaked and membered of such a tincture.

BEAM, in architecture, the largest piece of wood in a building, which lies across the walls, and serves to support the principal rafters of the roof, and into which the feet of these rafters are framed. No building has less than two of these beams, *viz.* one at each end. Into these the girders of the garret roof are also framed; and if the building is of timber, the teazle tenons of the posts are framed into them. The proportions of beams in or near London are fixed, by statute, as follows; a beam 15 feet long must be seven inches on one side its square, and five on the other; if it is 16 feet long, one side must be eight inches, the other six; and so proportionably to their lengths. In the country, where wood is more plenty, they usually make their beams stronger.

Beams of a ship are the great main cross timbers which hold the sides of the ship from falling together, and which also support the decks and orlops. The main beam is next the mainmast, and from it they are reckoned by first, second, third beam, &c. The greatest beam of all is called the midship beam. See Ship.

Beam *compass*, an instrument consisting of a square wooden or brass beam, having sliding sockets, that carry steel or pencil points; they are used for describing large circles, where the common compasses are useless.

Beam, in heraldry, the term used to express the main horn of a hart or buck.

Beam *filling*, in building, the filling up of the vacant space between the raison and roof, with stones or bricks laid between the rafters on the raison, and plastered on with loam, where the garrets are not pargeted, or plastered, as in country places.

Beam *of an anchor*, the longest part of it, called also the shank.

Beam also denotes the lath, or iron, of a pair of scales; sometimes the whole apparatus for weighing of goods is so called: thus we say, it weighs so much at the king's beam.

Beam *of a plough*, that in which all the parts of the plough tail are fixed. It is commonly made of ash, and is eight feet long; but in the four coultered plough it is ten feet long.

Beam, or roller, among weavers, a long and thick wooden cylinder, placed lengthwise on the back part of the loom of those who work with a shuttle. That cylinder on which the stuff is rolled as it is weaved, is also called the beam, or roller, and is placed on the fore part of the loom.

BEAN. See Vicia, and Phaseolis.

BEAR. See Ursus.

Bear, in astronomy, a name given to two constellations, called the greater and lesser bear, or ursa major and minor.

Bear, a species of barley cultivated in Scotland and Ireland, and the northern parts of England. It is not esteemed so good for malting as the common barley.

Bear, in heraldry. He that has a coat of arms is said to bear in it the several charges or ordinaries that are in his escutcheon.

BEAR'S *breech*. See Acanthus.

BEARER, in architecture, a post, or brick wall, trimmed up between the two ends of a piece of timber, to shorten its bearing, or to prevent its bearing with the whole weight at the ends only.

BEARING, in navigation and geography, the situation of one place from another, with regard to the points of the compass; or the angle which a line drawn through the two places makes with the meridians of each. The bearings of places on the ground are usually determined from the magnetic needle, in the managing of which consists the principal part of surveying; since the bearing or distance of a second point from a first being found, the place of that second is determined; or the bearings of a third point from two others, whose distance is known, being found, the place of the third is determined instrumentally; but to calculate trigonometrically, there must be more data.

Bearing, in the sea language. When a ship sails toward the shore, before the wind, she is said to bear in with the land or harbour. To let the ship sail more before the wind, is to bear up. To put her right before the wind, is to bear round. A ship that keeps off from the land is said to bear off. When a ship that was to windward comes under another ship's stern, and so gives her the wind, she is said to bear under her lee, &c. There is another sense of this word, in reference to the burden of a ship; for they say a ship bears, when having too slender or lean a quarter, she will sink too deep into the water with an over light freight, and thereby can carry but a small quantity of goods.

Bearing *of a piece of timber*, among carpenters, the space either between the two fixed extremes thereof, when it has no other support, which they call bearing at length, or between one extreme and a post, brick wall, &c. trimmed up between the ends to shorten its bearings.

BEAST, *la bête*, among gamesters, a game at cards, played in this manner: The best cards are the king, queen, &c. whereof they make three heaps, the king, the play, and triolet. Three, four, or five may play; and to every one are dealt five cards. However, before the play begins, every one stakes to the three heaps. He that wins most tricks, takes up the heap called the play; he that has the king, takes up the heap so called; and he that has three of any sort, that is, three fours, three fives, three sixes, &c. takes up the triolet heap.

BEAT of drum, in the military art, is to give notice by beat of drum, of a sudden danger; or, that scattered soldiers may repair to their arms and quarters, is to beat an alarm, or to arms; also to signify, by different manners of sounding a drum, that the soldiers are to fall on the enemy; to retreat before, in, or after, an attack; to move, or march, from one place to another; to treat upon terms, or confer with the enemy; to permit the soldiers to come out of their quarters at break of day; to order to repair to their colours, &c. is to beat a charge, a retreat, a march, &c.

BEAVER, in zoology. See Castor.

BECAH, or Bekah, in Hebrew antiquity, a Jewish coin, equal to thirteen and eleven sixteenths pence of our money.

BED, a place raised above the level of the floor of an apartment, on which the body is stretched out, for rest or sleep. (*a*)

All beds that are for sale must be filled with one sort of stuffing only, on the pain of forfeiture; as the mixing of feathers, down, scalded feathers, dry pulled feathers, any ways together, is conceived to be injurious to a man's body to lie on. Also bed quilts, mattresses, and cushions, stuffed with horse hair, fen down, goat's hair, and neat's hair, which are dressed in lime, and in which the heat of a man's body will exhale, and cause them to yield a noxious smell, are prohibited by statute.

Bed *of justice*, in the French customs, a throne upon which the king used to be seated when he went to the parliament. The king never held a bed of justice unless for affairs that concerned the state, and then all the officers of parliament were clothed in scarlet robes.

Bed *of the carriage of a great gun*, a thick plank that lies under the piece, being in fact, the body of the carriage.

Bed, in masonry, a course or range of stones; and the joint of the bed is the mortar between two stones placed over each other.

BEDCHAMBER, *lords of*, in the British customs, 14 lords who attend in their turns, each a week, during which time they lie in the king's bedchamber, and wait on him when he dines in private. Their salary is 1000*l.* per annum. The first of these is called groom of the stole. There are also twelve grooms of the bedchamber.

BEDA, a sacred book of the religion and laws of the brahmins of Hindostan, called also veda.

BEDOUINS, in the Arabian customs, tribes of Arabs, who live in tents, and are dispersed all over Arabia, Egypt, and the north of Africa.

BEE, in zoology. See Apis.

BEECH galls, hard protuberances found on the leaves of the beech, wherein are lodged the maggots of a certain fly. These galls are of an oblong figure and somewhat flatted. They resemble the stone of a plum in shape, and are very hard. In each gall there is a single cavity inhabited by a white worm, which in time passes through the nymph state into that of the fly, to which it owes its origin.

Beech *mast*, the fruit of the beech tree, said to be good for fattening hogs, deer, &c. and to have supplied men instead of bread. The island of Chios sustained a siege by means of mast.

Beech *oil*, an oil drawn by expression from the mast of the beech tree, after it has been shelled and pounded. This oil is very common in some parts of France, and used instead of butter; but most of those who take a great deal of it, complain of pains and a heaviness of the stomach.

BEELE, a kind of pickax, used by the miners for separating the ores from the rocks in which they lie: this instrument is called a tubber by the miners of Cornwall.

BEER, a common and well known liquor, made with malt and hops, and used in those parts of Europe where vines will not grow, and where cider is scarce. See Brewing, &c.

BEET, in botany. See Beta.

BEETLE, in entomology, a common English name for all insects that are furnished with shelly wing cases; those which have them divided by a straight suture are properly beetles, and belong to the coleoptera order. The scarabæi are beetles in the strictest sense of the word.

BEFARIA PANICULATA, in botany, a plant of the dodecandria, monogynia class and order; its characteristics are, cal. 7 cleft, corolla 7 pet. flower white, a native of Georgia. (*a*)

BEGGAR. See Vagrant.

BEGHARDI, a certain sect of Christians which arose in Germany, and in the low countries, about the end of the thirteenth century. They made profession of a monastical life, without observing celibacy; and maintained, if they are not scandalized by the monks, that man could become as perfect in this life as he shall be in heaven; that every intellectual nature is of itself happy, without the succour of grace; and that he who is in this state of perfection ought to perform no good works, nor worship the host.

BEGLERBEG, a governor of one of the principal governments in the Turkish empire. There are two sorts of beglerbegs; the one have a certain revenue assigned upon the cities, boroughs, and villages of their government, which they raise by power of the commission granted to them by the sultan; the others have a certain rent paid by the treasurer of the grand seignior. They are become almost independent, and have under their jurisdiction several sangiacs, or particular governments, and begs, agas, and other officers who obey them.

BEGONIA, in botany, a genus of plants of the monoecia polyandria class and order; the characters of which are: the flowers are of two kinds; the one is the male flower, with no cal. but many petals, some broader, and others narrower; the other, which produces the embryo fruit, is of the rosaceous sort, and is composed of several

petals, arranged in a circular form, and placed on a foliated cup, which finally becomes a trigonal alated caps. and containing small seeds. There are 13 species, chiefly stove plants.

BEGUINS, congregations of devout young women, who maintain themselves by the work of their hands, leading a middle kind of life between the secular and religious. These societies consist of several houses placed together in one enclosure, with one or more churches, according to the number of beguins. There is in every house a prioress, without whose leave they cannot stir out. Their vow is conceived in these terms: 'I promise to be obedient and chaste, as long as I continue in this beguinage.' They observe a three years' noviciate, before they take the habit; and the rector of the parish is their superior, but can do nothing without the advice of eight beguins. They were formerly established in several parts of Flanders.

BEHEADING, a capital punishment among the Romans: it was performed at first with an ax, but afterward with a sword, as was formerly the case in Holland and France. In France, however, during the last 15 years the guillotine has been used for the purpose of despatching criminals; and in the course of that space of time a multitude of the most loyal, virtuous, and most honourable men in Europe, for actions the most praiseworthy, have been cruelly murdered by that instrument.

BEHEN, in the materia medica, the name of two roots, the one white the other red, both accounted cordials and restorative.

BEJARIA, a genus of the dodecandria monogynia class and order: the essential character is; calyx seven cleft; petals seven; stam. fourteen; berry seven celled, many seeded.

There are two species, one a tree and the other a shrub, of New Granada. The tree has purple flowers, and the shrub flesh coloured, something allied to the rhododendrons.

BEIZA, or Beizath, in Hebrew antiquity, a word signifying an egg, was a certain measure in use among the Jews. The beiza was likewise a gold coin, weighing forty drachms, among the Persians.

BELAY, in the sea language, is to make fast the ropes in their proper places.

BELEMNITES, in natural history, are fossils, composed of several thin coats or crusts, encircling one another, and all of a striated texture; they have usually a hollow in the middle, of a conical shape; sometimes empty, and sometimes filled up with spar, pyrites, or a marine shell of the straight concamerated kind. They have usually a chink running down the whole length of the body, and sometimes two or three; but the additional ones usually begin at the apex of the stone, and run up but a little way. Their figure is sometimes conic, sometimes cylindric: some are of all the intermediate figures between conic and cylindric, and some almost orbicular. They are of various sizes, from a quarter of an inch to eight inches in length, and though always of the same structure, are of various colours, and they have a peculiar smell when scraped. They are found in all sorts of strata, sometimes in clay, sometimes among gravel, often immersed in beds of stone, often in loose flints, and are sometimes found covered with a sparry crust of a different texture from the body of the mass. The finest specimens have been procured from chalk pits of Oxfordshire.

BELL, a well known machine, ranked by musicians among the musical instruments of percussion. The music of bells is altogether melody; but the pleasure arising from it consists in the variety of interchanges, and the various successions and general predominance of the consonances in the sounds produced. The metal of which a bell is made, is a composition of tin and copper, or pewter and copper; the proportion of one to the other is almost 20 pounds of pewter, or 23 pounds of tin, to 100 weight of copper. Bell metal is prohibited to be imported, as are hawk bells, &c.

The constituent parts of a bell are the body or barrel, the clapper on the inside, and the ear or cannon on which it hangs to a large beam of wood. The sound of a bell consists in a vibratory motion of its parts, much like that of a musical chord. The stroke of the clapper must necessarily change the figure of the bell, and of a round make it oval; but the metal having a great degree of elasticity, that part will return back again which the stroke drove furthest off from the centre, and that even some small matter nearer the centre than before; so that the two parts which before were extremes of the longest diameter, do then become those of the shortest; and thus the external surface of the bell undergoes alternate changes of figure, and by that means gives that tremulous motion to the air, in which the sound consists. To understand this more completely, let us conceive that a bell is composed of a series of circular zones, decreasing in diameter all the way to its top, each of which may be considered as a flat ring, composed of as many concentric circles as its thickness will admit of. If this ring is struck at the point *a*, Plate XXXIX. Miscel. fig. 11. the part so struck tends toward *g*, and at the same time the parts *b* and *d* tend toward *i* and *m*, and this action in these parts necessarily causes the point *c* to approach toward *e*; by their elastic power, however, these parts presently regain the position in which they were before the bell was struck; but as they return with an accelerated force, they generally go beyond the point where they ought to rest. The part *a*, therefore, after having returned from *g* to *a*, tends toward *f*, the part *c* toward *h*, and the parts *b* and *d* toward *k* and *l*; whence it happens that the bell, at first of a circular form, really becomes alternately oval in two different directions; it follows then, that in those parts where the curvature is the greatest, their exterior points depart from each other.

BELLA DONNA. See Amaryllis and Atropa.

BELLES-LETTRES, a word absurdly introduced from the French, and noted here only to reprobate the contemptible practice of debasing the simple majesty of our native language, by wretched gallicisms. The French writers themselves have no determinate idea affixed to this phrase; some applying it to polite literature only, and some extending it to the whole scope of human learning, even to mathematics.

BELLIS, in botany, the daisy, a genus of the syngenesia class, and polygamia superflua order of plants; and in the natural method ranking under the 49th order, compositæ discoidæ. The receptacle is naked and conic; there is no pappus; the calyx is hemispherical, with equal scales; and the seeds are ovated. There are two species, and many varieties.

1. Bellis annua, with leaves on the lower part of the stalk, is a low annual plant growing naturally on the Alps and the hilly parts of Italy. It seldom rises more than three inches high, and has an upright stalk, with leaves on the lower part; but the upper part is naked, supporting a single flower, like that of the common daisy, but smaller.

2. Bellis perennis, the common daisy, with a naked stalk, and one flower, grows naturally in pasture lands in most parts of Europe. It is often a troublesome weed in the grass of gardens, so is never cultivated. Its leaves have a subtile subacid taste; and are recommended as vulneraries, and in asthmas and hectic fevers, as well as in such disorders as are occasioned by drinking cold liquors when the body has been much heated.

The Bellis hortensis, or garden daisy, is only a variety of this species. It has a large double flower. The varieties cultivated in gardens are; 1. the red and white garden daisy: 2. the double variegated garden daisy: 3. the childing, or hen and chicken garden daisy: and 4. the cock's comb daisy, with red and white flowers.

BELLIUM, a genus of the syngenesia, polygamia superflua class and order. The essential character is; cal. with equal leaflets; seeds conic, with chaffy eight leaved crown, and awned down; recept. naked. There are two species, natives of Italy and the Levant, in many respects resembling the daisy in habit and appearance.

BELLON, a distemper common in countries where they smelt lead ore. It is attended with languor, intolerable pains, and sensation of gripings in the belly, and generally costiveness. Beasts, poultry, &c. as well as men, are subject to this disorder. Hence a certain space round the smelting houses is called bellon ground, because it is dangerous for an animal to feed upon it.

BELLONIA, in botany, a genus of the monogynia order, and pentandria class of plants. The characters are; the flower is wheel shaped; the germen is situated under the receptacle of the flower, which afterward becomes a turbinated seed vessel, ending in a point, having one cell filled with small round seeds. Of this genus there are two species known, *viz.*

1. Bellonia aspera, or shrubby bellonia, has a rough balm leaf. It is very common in the warm islands of America.

2. Bellonia spinosa, a native of Hispaniola.

BELLOWS, a machine so contrived, as to agitate the air with great briskness, expiring and inspiring the air by turns, and that only from enlarging and contracting its capacity. This machine is of various constructions, but in general is composed of two flat boards, sometimes of an oval, sometimes of a triangular figure: two or more hoops, bent according to the figure of the boards, are placed between them; a piece of leather, broad in the middle, and narrow at both ends, is nailed on the edges of the boards, which it thus unites together, as also on the hoops which separate the boards, that the leather may the easier open and fold again; a tube of iron, brass, or copper, is fastened to the undermost board; and there is a valve within that covers the holes in the under board, to keep in the air. In founderies, and other great works, where a constant and vast heat is required, the bellows are made double, so that there is a constant blast proceeding by the upward and downward motion of the handle.

The action of bellows, however wrought, whether by water, steam, or men, depends on this; that the air which enters them, and which they contain when raised, is again compressed into a narrower space when they are closed, and it flows out of the pipe with a velocity proportional to the force by which it is compressed. The blast also will last in the proportion which the quantity of air drawn in through the valve bears to the pipe. The bellows of smiths and founders are worked by means of a rocker, with a string or chain fastened to it, and pulled by the workman. One of the boards is fixed, and by drawing down the handle of the rocker, the moveable board rises, and by means of a weight on the top of the upper board, sinks again. The bellows of an organ are wrought by a man called the blower; but in small organs, by the foot of the player.

BELLY, the abdomen. See Anatomy.

BELTS, in astronomy, two zones, or girdles, surrounding the body of the planet Jupiter, more lucid than the rest, and of unequal breadth. See Astronomy.

Belts, in geography, certain straits between the German Ocean and the Baltic. The belts belong to the king of Denmark, who exacts a toll from all ships which pass through them, excepting those of Sweden, which are exempted.

BENCAPED, among sailors. A ship is said to be bencaped when the water does not flow high enough to bring her off the ground, out of the dock, or over the bar.

BENCH, *free*, signifies that estate in copyhold lands, which the wife, being espoused a virgin, has after the decease of her husband, for her dower, according to the custom of the manor. As to this free bench, several manors have their own customs; and in the manors of East and West Enbourne, in the county of Berks, and other parts of England, there is a custom, that when a copyhold tenant dies, the widow shall have her free bench in all the deceased husband's lands, whilst she lives single and chaste; but if she commits incontinency, she shall forfeit her estate: nevertheless, upon her coming into the court of the manor, riding on a black ram, and having his tail in her hand, and at the same time repeating a form of words prescribed, the steward is obliged, by the custom of the manor, to re-admit her to her free bench.

BEND, in heraldry, one of the nine honourable ordinaries, containing a third part of the field when charged, and a fifth when plain. It is sometimes, like other ordinaries, indented, ingrailed, &c. and is either dexter or sinister.

BENDING, in the sea language, the tying two ropes or cables together: thus they say, bend the cable; that is, make it fast to the ring of the anchor: bend the sail, make it fast to the yard.

BENDS, in a ship, the same with what is called wails, or wales; the outmost timbers of a ship's side, on which men set their feet in climbing up. They are reckoned from the water, and are called the first, second, or third bend. They are the chief strength of a ship's sides, and have the beams, knees, and foot hooks, bolted to them.

BENEDICTINES, in church history, an order of monks, who profess to follow the rules of St. Benedict. The Benedictines being those only that are properly called monks, wear a loose black gown, with large wide sleeves, and a capuche, or cowl, on their heads, ending in a point behind. In the canon law they are styled black friars, from the colour of their habit.

The rules of St. Benedict, as observed by the English monks before the dissolution of the monasteries, were as follows: they were obliged to perform their devotions seven times in 24 hours, the whole circle of which devotions had respect to the passion and death of Christ: they were obliged always to go two and two together: every day in Lent they were obliged to fast till six in the evening, and abated of their usual time of sleeping and eating; but they were not allowed to practise any voluntary austerity without leave of their superior; they never conversed in their refectory at meals, but were obliged to attend to the reading of the Scriptures: they all slept in the same dormitory, but not two in a bed; they lay in their clothes. For small faults they were shut out from meals; for greater, they were debarred religious commerce, and excluded from the chapel; and as to incorrigible offenders, they were excluded from the monasteries. Every monk had two coats, two cowls, a table book, a knife, a needle, and a handkerchief: and the furniture of their bed was a matt, a blanket, a rug, and a pillow.

BENEFICE, a church endowed with a revenue, for the performance of divine service; or the revenue itself assigned to an ecclesiastical person, by way of stipend, for the service he is to do that church.

All church preferments, except bishoprics, are called benefices; and all benefices are, by the canonists, sometimes styled dignities; but we now ordinarily distinguish between benefice and dignity; applying dignity to bishoprics, deaneries, archdeaconries, and prebends; and benefice to parsonages, vicarages, and donatives.

The canonists distinguish three manners of vacating a benefice, *viz.* de jure, de facto, and by the sentence of a judge. A benefice is vacated de jure, when the person enjoying it is guilty of certain crimes expressed in those laws, as heresy, simony, &c. A benefice is vacated de facto as well as de jure, by the natural death or the resignation of the incumbent; which resignation may be either express, or tacit, as when he engages in a state, &c. inconsistent with it, as, among the Romanists, by marrying, entering into a religious order, or the like. A benefice becomes vacant by the sentence of a judge, by way of punishment for certain crimes, as concubinage, perjury, &c.

In the church of England there are 1071 benefices under 10*l.* per annum; 1467 from 10 to 20; 1126 from 20 to 30; 1049 from 30 to 40; 884 from 40 to 50; and there are 5597 livings under 50*l.* per annum. It must be 500 years before every living can be raised to 60*l.* a year by queen Anne's bounty, and 339 years before any of them can exceed 50*l.* a year. On the whole, there are above 11,000 church preferments in England, exclusive of bishoprics, deaneries, canonries, prebends, priest vicars, lay vicars, secondaries, &c. belonging to cathedrals, or choristers, or even curates to well beneficed clergymen. Benefices began about A.D. 500.

BENISH *days*, among the Egyptians, a term of three days of the week, which are days of less ceremony in religion than the other four.

BENZOIN, a dry and solid resin, brought to us in masses of various sizes from the East Indies, particularly from the kingdom of Siam, and the islands of Java and Sumatra. It is very brittle, and breaks vitreous. When rubbed, it emits a fragrant odour, and when heated sufficiently, lets the benzoic acid escape. It is soluble in alcohol, but insoluble in water. It is used chiefly to perfume apartments, and benzoic acid is extracted from it. It has not been examined by any modern chymist. Its specific gravity is 1.092. It is considered as a compound of resin and benzoic acid. See STYRAX, and for benzoic acid see CHYMISTRY.

BERAMS, a coarse cloth, all made with cotton thread, which comes from the East Indies, and particularly from Surat.

BERBERIS, the barberry, or pipperidge bush. A genus of the monogynia order, and hexandria class of plants: the characters of which are; the calyx consists of six leaves; the petals are six, with two glands at the ungues; it has no stylus; and the berry contains two seeds. The species are four:

1. Berberis cretica, with a single flower in each footstalk, is at present very rare in Britain; the plants being tender whilst young, and most of them killed by severe frost. This never rises more than three or four feet high in England; but sends out many stalks from the root, which are strongly armed with spines at every joint: the leaves are produced without order, and are shaped like those of the narrow leaved box tree; the flowers come out from between the leaves, each having a slender footstalk; but they are not succeeded by fruit in Britain.

2. Berberis illicifolia, with leaves like the holm oak.

3. Berberis Sibirica, a very small shrub, scarcely a span in height.

4. Berberis vulgaris, the common barberry, which grows naturally in hedges in many parts of England; but is also cultivated in gardens, on account of its fruit, which is pickled. It rises to the height of eight or ten feet, with many stalks, which have a white bark, yellow on the inside. The flowers come out from the wings of the leaves in small ramose bunches like those of the currant bush, and are of a yellow colour; these are succeeded by oval fruit, which are at first green, but when ripe turn to a fine red colour. The flowers appear in May, and the fruit ripens in September. There are two or three varieties of this shrub, which by some have been taken for distinct species; one is the barberry without stone; another, the barberry with white fruit; and a third is called by Tournefort taller eastern barberry, with a black sweet fruit. Of these Mr. Miller observes, that the first certainly depends on the age of the plant, because the suckers taken from those bushes commonly produce fruit with stones. The second, he says, seldom bears any fruit; the leaves are of a lighter green colour, and the bark of the stalks is whiter, than those of the common kind. The third appears to be the same with the common sort, excepting the colour and flavour of its fruit, which can never indicate a specific difference. The berries, which are so acid that birds will not feed upon them, are moderately astringent; and have been given with success in bilious fluxes, and diseases proceeding from heat, acrimony, and thinness of the juices. The leaves also are gratefully acid. The flowers are offensive to the smell when near, but at a distance their odour is extremely fine. An infusion of the bark in white wine is purgative. The roots boiled in lye, dye wool yellow. In Poland they dye leather of a most beautiful yellow with the bark of the root. The inner bark of the stems dyes linen of a fine yellow with the assistance of alum. This shrub should never be permitted to grow in corn lands; for the ears of wheat that grow near it never fill, and its influence in this respect has been known to extend across

a field of 300 or 400 yards. Cows, sheep, and goats, eat it: horses and swine refuse it.

BERCHEROIT, or Berkcoits, a weight used at Archangel, and in all the Russian dominions: it weighs about 364 pounds English avoirdupois weight.

BERDASH, a name formerly used in England for a certain kind of neck dress; and hence a person who made or sold such neck cloths, was called berdasher, from which is derived our word haberdasher.

BERENGARIANS, a religious sect of the 11th century, which adhered to the opinion of Berengarius, who, even in those days, strenuously asserted, that the bread and wine in the Lord's supper is not really and essentially, but only figuratively, changed into the body and blood of Christ.

BERGAMOT, the name of a fragrant essence extracted from a species of citron. As this oil exists pure in the peel, being simply deposited in small cells, the extraction is easy, either by expression or distillation. The former is the best, as the oil is not liable to be altered by heat; but more is produced by distillation than by expression: by this mode two ounces of the oil have been obtained from two pounds of the peel.

It is also the denomination of a coarse tapestry, manufactured with flocks of silk, wool, cotton, hemp, ox, cow, or goat's hair, and supposed to be invented by the people of Bergamo.

BERGESA, a genus of the class and order decandria monogynia. The essential character is, calyx five parted; petals five; berry subglobular, one celled, with five seeds. There is one species, a leafy tree, with the bark of the alder: a native of the East Indies.

BERGIA, a genus of the class and order decandria pentagynia. The essential character is, calyx five parted; petals five; capsule one, globular, with swellings, five celled, five valved, valves resembling petals; seeds many.

There are two species, the B. capensis and glomerata, both natives of the Cape.

BERGHMOT, an assembly, or court, held upon a hill, in Derbyshire, for deciding controversies among the miners.

BERIBERI, a kind of palsy, common in the East Indies. The word, in the language of the country, signifies a sheep; and was given by the natives to this distemper, because the patients, on throwing out their knees, and lifting up their legs, seem to imitate sheep in their walk.

BERME, in fortification, a space of ground left at the foot of the rampart, on the side next the country, designed to receive the ruins of the rampart, and prevent the filling up of the fosse. It is sometimes palisadoed, for the more security; and in Holland it is generally planted with a quickset hedge. It is also called liziere, relais, foreland, retraite, pas de souris, &c.

BERNARDINES, an order of monks, founded by Robert abbot of Moleme, and reformed by St. Bernard. They wear a white robe with a black scapulary; and when they officiate, they are clothed with a large gown, which is all white, and with great sleeves, and a hood of the same colour. They differ but very little from the Cistercians.

BERNHARDIA DICHOTOMA, in botany, a plant of cryptogamia class and order filices. (*a*)

BERRY, a round fruit, for the most part soft, and covered with a thin skin, containing seeds in a pulpy substance; but if it is harder, or covered with a thicker skin, it is called pomum, apple.

BERTIESA, a genus of the pentandria monogynia class and order. The essential character is, calyx turbinate, five toothed; corolla, tube short, with a villose mouth; berry globose, inferior, two celled, many seeded.

There is but one species, the B. Guianensis, which the specific name announces to be a native of Guiana. The flower is white.

BERYL, in natural history, called by our lapidaries aqua marina, is a pellucid gem of a bluish green colour, found in the East Indies and about the gold mines of Peru, and especially in Siberia and Tartary, where its crystals are sometimes a foot long.

The beryl, like most other gems, is met with both in the pebble and columnar form, but in the latter most frequently. In the pebble form it usually appears of a roundish but flatted figure, and commonly full of small flat faces, irregularly disposed. In the columnar or crystaline form it always consists of hexangular columns, terminated by hexangular pyramids. It never receives any admixture of colour into it, nor loses the blue and green, but has its genuine tinge in the degrees from a very deep and dusky to the palest imaginable of the hues of sea water.

The beryl has many points of resemblance with the emerald, and in particular the crystals of both are divisible parallel to the sides and extremities of a regular hexahedral prism. The beryl is externally shining, with a vitreous lustre. It is generally transparent, but sometimes only semi-transparent. The specific gravity varies from 2.65 to 2.75. A specimen, analyzed by Vauquelin, contained

69	silica
13	alumina
16	glucina
1	oxide of iron
0.5	lime
99.5	

It was by the analysis of this stone that Vauquelin discovered the earth which he called glucina. The beryl, when cut and polished, has a considerable lustre: it is ranked among gems; but its value is trifling, compared with the ruby, sapphire, topaz, &c.

Beryl crystal, in natural history, a species of what Dr. Hill calls ellipomacrostyla, or imperfect crystals, is of an extremely pure, clear, and equal texture, and scarcely ever subject to the slightest films or blemishes. It is ever constant to the peculiarity of its figure, which is that of a long and slender column, remarkably tapering toward the top, and very irregularly hexangular. It is of a very fine transparency, and naturally of a pale brown; and carries such evident marks of distinction from all other brown crystals, that our lapidaries call it, by way of eminence, the beryl crystal, or simply the beryl.

BESANT, or *bezant*, a coin of pure gold, of an uncertain value, struck at Byzantium, in the time of the Christian emperors: hence the gold offered by the king at the altar, is called besant, or bisant.

Few coins ever had a more general currency than these besants; having been current from the beginning to the

end of the eastern empire, in all its provinces, and also in those countries that had been provinces of the western empire; and among others in Britain. With us they were received in payments. They are frequently referred to by the historians of the crusades, but are rarely mentioned by ours; and are not to be found in Doomsday book, nor in the acts of Henry I. or Stephen, nor in the last will of king Henry II.

Besants, in heraldry, round pieces of gold, without any stamp, frequently borne in coats of arms.

BESISTAN, a name given to those places at Constantinople, &c. where the merchants have their shops, and expose their goods to sale. A particular besistan belongs to each class of merchants.

BESLERIA, a genus of the angiospermia order and didynamia class of plants. Of this genus there are six species: the most remarkable are,

1. Besleria cristata, with stalks growing single, and a five leaved involucrum. The calyx is scarlet, the corolla yellow.

2. Besleria lutea, with simple footstalks growing in clusters, and spear shaped leaves; yellow flowers.

3. Besleria melittifolia, with branching footstalks and oval leaves. All these species are natives of the warm parts of America, and cannot be preserved in this country without artificial heat. But as they are not remarkable for beauty, or any other property yet discovered, we forbear any particular description.

BESORCH, a coin of tin, or some alloyed metal, current at Ormus, at the rate of 7-49th parts of a farthing sterling.

BESTIARII, in Roman antiquity, such as fought against beasts, or who were exposed to them by sentence of the law. There were four kinds of bestiarii: the first were those who made a trade of it, and fought for money; the second were such young men as, to show their strength and dexterity in managing their arms, fought against beasts; the third was where several bestiarii were let loose at once, well armed, against a number of beasts; and the fourth kind were those condemned to the beasts, consisting either of enemies taken prisoners in war, or as being slaves, and guilty of some enormous crime: these were all exposed naked, and without defence.

BETA, a genus of the pentandria digynia class and order of plants; and in the natural method ranking under the 12th order, holoraceæ. The calyx has five leaves; there is no corolla; the seeds are kidney shaped, and situated within the base of the calyx. There are four species, *viz.*

1. Beta cicla, the root of scarcity, has been greatly extolled in different publications of late years: but its virtues have perhaps been exaggerated. The beta hortensis, or common white beet, is a variety of this; and is cultivated in gardens for the sake of its leaves, which are frequently used in soups.

2. Beta maritima, the sea beet, grows naturally by the sea side, in salt marshes, and in many parts of England. It has been supposed by many to be only a variety of the common white beet; but Mr. Miller assures us he has been unable to make any variation in them by culture.

3. B. apatula, a native of Madeira.

4. Beta vulgaris, the red beet, with a pyramidal root, has large, thick, succulent leaves, which are for the most part of a dark green or purple colour. The roots are large, and of a deep red. The larger these roots grow, the tenderer they are; and the deeper their colour, the more they are esteemed. The varieties of this species are the common red beet, the turnip rooted beet, and the green leaved red beet.

On many parts of the continent the beet root has been used for the purpose of extracting sugar from it. The roots are pressed, and the saccharine liquor boiled down to the consistence of a syrup: it of course undergoes many other operations. According to the account of M. Achard, however, the cost of a quantity of beet, in Prussia, that will yield one hundred pounds of raw sugar, is not more than sixpence: twenty pounds of root will yield one of sugar; one hundred pounds of raw sugar give fifty-five of refined, and twenty-five pounds of molasses. It is computed by the same gentleman, who has employed much time in the pursuit, that a German square mile of land, that is, sixteen square miles English, properly cultivated, would produce white beet sufficient to furnish the whole Prussian dominions with sugar.

BETEL, or *betle*, in botany, a kind of long pepper, found in Malabar, and other parts of the East Indies. See Piper.

BETELGEULE, a fixed star of the first magnitude, in Orion's hind shoulder.

BETHLEHEMITES, in church history, a religious order, called also star bearers, *stelliferi*, because they were distinguished by a red star with five rays, which they wore on their breast, in memory of the star that appeared to the wise men, and conducted them to Bethlehem.

There is an order of Bethlehemites still subsisting in the Spanish West Indies, who are habited like capuchins, with this difference; that they wear a leathern girdle instead of a cord, and on the right side of their cloak an escutcheon, representing the nativity of our Saviour.

BETONICA, *betony*, a genus of the gymnospermia order and didynamia class of plants, and in the natural method ranking under the 42d order, verticillatæ. The calyx is awned; the upper lip of the corolla is ascending and flattish: and the tube is cylindric. There are seven species. The most remarkable are,

1. Betonica orientalis, the oriental betony.

2. Betonica stricta, the greater Danish betony.

3. Betonica incana, the hoary Italian betony, has a flesh coloured flower.

4. Betonica officinalis, is the species chiefly worth notice. It is a low plant, growing in woods and shady places in several parts of England; the flowers come forth in June and July, of a purplish colour, and stand in spikes on the top of the stalks. The leaves and flowers have a roughish, somewhat bitterish taste, accompanied with a very weak aromatic flavour. The powder of the leaves of betony snuffed up the nose provokes sneezing; and hence it is sometimes made an ingredient in sternutatory powders. This effect does not seem to be owing, as is generally supposed, to any peculiar stimulating virtues in the herb, but to the rough hairs with which the leaves are covered. The roots of this plant differ greatly in the quality from the other parts: their taste is very bitter and nauseous: taken in a small dose, they vomit and purge violently, and are supposed to have somewhat in common

with the root of hellebore. According to Simon Pauli and Bartholinus, this plant affects those who gather any considerable quantity of it with a disorder resembling drunkenness. Its leaves are sometimes smoked like tobacco.

BETROTHMENT, among civilians, the same with espousals.

BETULA, the birch or alder tree, a genus of the tetandria order and monoecia class of plants, and in the natural method ranking under the 50th order, amentaceæ. The calyx of the male is monophyllous, trifid, and biflorous; and the corolla is parted into four segments: the female calyx is monophyllous, trifid, and biflorous: the seeds have a membranaceous wing on both sides. There are fifteen species: the more remarkable are,

1. Betula alba, the common birch tree, so well known to *young students* as to need no description: in a proper soil and situation it will rise high, and swell to a considerable size. There is a spruceness in its general appearance in summer; and in winter its bark often exhibits, in its variegations of red and white, no inelegant object. Were it not so commonly seen upon poor soils, and applied to so many mean and degrading purposes, the birch might well claim a place among the ornamental trees.

2. Betula alnus, the alder tree, will grow to a large timber tree. The alder is of straggling inelegant growth; and hacked and disfigured in the manner in which they generally are, they have but little effect in effacing the unsightliness of a swamp, which is their natural soil. Wherever the soil is or can be made pasturable, the alder should by no means be permitted to gain a footing. Its suckers and seedlings poison the herbage; and it is a fact well known to the observant husbandman, that the roots of the alder have a peculiar property, of rendering the soil they grow in more moist and rotten, than it would be if not occupied by this aqueous plant. Plantations of alders should therefore be confined to swampy, low, unpasturable places. In this case the native species ought to give place to its more ornamental varieties, of which Hanbury enumerates five; *viz.* 1. the long leaved, 2. the white, 3. the black, 4. the hoary leaved, and 5. the dwarf alder.

3. Betula lenta, the Canada birch, grows to sixty or more feet in height. The leaves are heart shaped, oblong, smooth, of a thin consistence, pointed, and very sharply serrated. They differ in colour; and the varieties of this species are, 1. dusky Canada birch; 2. white paper birch; 3. poplar leaved Canada birch; 4. low growing Canada birch, &c.

4. Betula nana, the dwarf birch, with roundish leaves, grows naturally in the northern parts of Europe and on the Alps. It seldom rises above two or three feet high. It has slender branches with round leaves, but seldom produces flowers here. It is preserved in some curious gardens for the sake of variety, but is a plant of no use.

5. Betula nigra, the black Virginian birch tree, will grow to upward of 60 feet in height. The branches are spotted, and more sparingly set in the trees than the common sorts. The leaves are broader, grow on long footstalks, and add a dignity to the appearance of the tree. As it is naturally of an upright and swift growth, and arrives at so great a magnitude, Hanbury thinks it ought to have a share among our forest trees, and to be planted for the standards in open places, as well as to be joined with other trees of its own growth, in plantations more immediately designed for relaxation and pleasure. There are several varieties of this species, differing in the colour, size of the leaves, and shoots; such as, 1. the broad leaved Virginian birch, 2. the poplar leaved birch, 3. the paper birch, 4. the brown birch, &c.

One method of propagating the foreign sorts of birch is from seeds: but they may also be propagated by layers; and this is the way to continue the peculiarities in the varieties of the different sorts. In autumn the young shoots should be plashed near the stools, and they will strike root, and become good plants by the autumn following.

In some of the northern parts of Europe the wood of the white birch is much used for making carriages and wheels, being hard and of long duration. In France it is generally used for making wooden shoes, and in Britain for making women's shoe heels, packing boxes, brooms, hoops, &c. It also makes very good fuel, and is planted along with hazel to make charcoal for forges. The bark of the birch seems in a manner incorruptible. In Sweden the houses are covered with it, and it lasts many years. It frequently happens that the wood is entirely rotten, when the bark is perfectly sound and good. In Kamtschatka it is used for making drinking cups. It abounds with a resinous matter, to which its durability is certainly owing. In consequence of this, it is highly inflammable: and in the northern countries torches are made of this bark sliced and twisted together. The bark itself consists of two different substances; a thick brittle brownish red one; and several very thin, smooth, white, transparent membranes; in which the inflammable property resides. The thick part is less resinous, and has a roughish taste. It has been thought to possess some medical virtues, but concerning these experience has as yet determined nothing certain. Upon deeply wounding or boring the trunk of the tree in the beginning of spring, a sweetish juice issues, sometimes in so large a quantity as to equal the weight of the whole tree and root; one branch will bleed a gallon or more in a day. This juice is recommended in scorbutic disorders, and other foulnesses of the blood. Its most sensible effect is to promote the urinary discharge. By proper fermentation, with the addition of sugar, this juice makes a pleasant wine. The bark of the Canada birch is very light, tough, and durable; and the inhabitants of America use it for canoes.

BEVEL, among masons, carpenters, joiners, and bricklayers, a kind of square, one leg whereof is frequently crooked, according to the sweep of an arch or vault. It is moveable on a centre, and so may be set to any angle. The make and use of this instrument is pretty much the same as those of the common square and mitre, except that those are fixed, the first at an angle of ninety degrees, and the second at forty-five; whereas the bevel being moveable, it may in some measure supply the place of both, which it is chiefly intended for, serving to set off or transfer angles, either greater or less than ninety or forty-five degrees.

Bevel angle, any angle except those of ninety or forty-five degrees.

BEVELLING, in ship building, the art of hewing timber with a proper and regular curve, according to a mould which is laid on one side of its surface.

BEVILE', in heraldry, a thing broken or opening like a carpenter's rule: thus we say, he beareth argent, a chief bevilé, vert, by the name of beverlis.

BEY, among the Turks, signifies a governor of a country or town. The Turks write it begh, or bek, but pronounce it bey.

BEZANS, cotton cloths, which come from Bengal: some are white, and others striped with several colours.

BEZOAR, originally meant an antidote, or medicine intended to prevent the fatal effects of poison.

Bezoar, *oriental*, a moderately hard and heavy stone, very variable and uncertain in size, shape, and colour. It is generally of a round form; and its size is between that of a horse bean and that of a small walnut, though there are some larger, and others smaller than peas. The ordinary colour is a duskish olive, or greenish brown. It is always smooth and glossy on the surface; and, when broken, is found to consist of a great number of coats or crusts of stony matter, laid one over another; and often formed upon a piece of stick, or seed of a fruit, or some such article, for a nucleus or basis. This is a drug of very great price, and of very great fame: but it is not of the number of those things that have been proved to deserve the repute they stand in. It is brought to us from Persia, and many parts of the East Indies: it is to be chosen entire, not in scraps or fragments; of a greenish or olive colour, with some mixture of gray in it; and such as, when rubbed on paper, before whitened with ceruss, gives a yellowish colour. There is also an occidental bezoar, which comes from Mexico.

Bezoars are generally supposed to be concretions formed in the stomach or intestines of different graminivorous animals; but it is not completely ascertained in what animal they are found, or how many species may yield them. Dr. Pearson analyzed one specimen, and found it entirely composed of vegetable matter. Several writers attribute very great virtues to the oriental bezoar; but it is probable that if it has any action at all, it is merely that of an absorbent earth, as chalk or magnesia.

BIA, in commerce, a name given by the Siamese to those small shells which are called cowries throughout almost all the other parts of the East Indies. See Cowrie.

BICE, or *bise*, among painters, a blue colour prepared from the lapis armenus.

Bice bears the best body of all bright blues used in common work, as house painting, &c. but it is the palest in colour. It works indifferently well, but inclines a little to sandy, and therefore requires good grinding. Next to ultramarine, which is too dear to be used in common work, it lies best near the eye of all other blues.

BICEPS, in anatomy, the name of several muscles. See Anatomy.

BIDENS, a genus of the syngenesia polygamia æqualis class and order, and in the natural method ranking under the 49th order, compositæ oppositifoliæ. The receptacle is paleaceous; the pappus has erect scabrous awns; and the calyx is imbricated. Of this genus there are fourteen species; but none of them appear to merit notice, except the Bidens tripartita, frequently found by the sides of rivulets, ditches, and lakes, in England. It grows to the height of two feet; and has its leaves divided into three, or often five, lobes, with yellow flowers. A decoction of this plant with alum, dyes yarn of a yellow colour. The yarn must be first steeped in alum water, then dried and steeped in a decoction of the plant, and afterward boiled in the decoction.

BIDON, a liquid measure, containing about five pints of Paris, that is, about five quarts English wine measure. It is seldom used but among ship's crews.

BIENNIAL *plants*, are those that have two years duration, or that are in their prime the first and second summers. They consist both of esculent and flowering plants.

BIGAMY, in the canon law, is when a person either marries two women successively, or only marries one woman who had been married before; both which cases are accounted impediments to be a clerk, or to hold a bishoprick. It is also bigamy when a person marries a woman who had been debauched before; or when he has known his own wife after she has been debauched by another.

The Romanists make a kind of bigamy by interpretation: as when a person in holy orders, or that has made profession of some monastic order, marries. This the bishop can dispense with on some occasions.

Bigamy, by the law of England, is where a person marries a second wife, the first being alive. By the stat. 1 Jac. I. c. 11, it is enacted, that if any person or persons within his majesty's dominions, being married, do marry any person or persons, the former husband or wife being alive, the person or persons so offending shall suffer death, as in cases of felony. But it is provided, that nothing in this statute shall extend to any person or persons whose husband or wife shall be continually remaining beyond seas by the space of seven years together, or whose husband or wife shall absent himself or herself from each other for seven years together, the one of them not knowing the other to be living within that time. Nor shall the said statute extend to any person or persons divorced by a sentence in the ecclesiastical court; nor to any person or persons, for or by reason of any former marriage had or made within age of consent. The offence is now within the benefit of clergy.

BIGHT, among seamen, denotes one roll, or round, of a cable or rope, when coiled up.

BIGNONIA, *trumpet flower*, or *scarlet jasmine*, a genus of the angiospermia order and didynamia class of plants, and in the natural method ranking in the 40th order, personatæ. The calyx is quinquefid and cupform; the corolla is bell shaped at the throat, quinquefid, and bellied underneath; the siliqua is bilocular; and the seeds have membranous wings. Of this genus there are 27 species, of which the following are the most remarkable:

1. Bignonia catalpa, a native of Carolina, Virginia, and the Bahama islands. It has a strong woody stem and branches, rising 20 feet high, ornamented with large heart shaped leaves. This deserves a place in all curious shrubberies, as during the summer season no tree makes a more beautiful appearance. It does not flower, however, till old.

2. Bignonia capreolata, or tendril bignonia, a native of North America, is a climber, which rises by the assistance of tendrils or claspers. The flowers are produced in August from the wings of the leaves: they are of the same nature, and of the shape nearly of the former; are large, of a yellow colour, and succeeded by short pods.

3. Bignonia radicans, the climbing ash leaved bignonia, is a native of Virginia and Canada, rises 30 or 40 feet high,

having pinnated opposite leaves of four pair of serrated lobes, and an odd one: all the shoots and branches being terminated by beautiful clusters of large trumpet shaped scarlet flowers. The humming birds delight to feed on these flowers; and by thrusting themselves too far into them are sometimes caught. Of this species there is a variety with smaller flowers.

4. Bignonia sempervirens, or evergreen climbing Virginia bignonia, is a native of Virginia, Carolina, and the Bahama islands. The stalks are more slender than those of the radicans, yet they rise, upon proper supports, to the height of twenty or thirty feet; the flowers are trumpet shaped, erect, and of a yellow colour, proceeding from the sides and ends of the stalks and branches.

5. Bignonia unguis, the claw bignonia, a deciduous climber, is a native of Barbadoes and the other West India islands. It rises by the help of claw like tendrils, the branches being very slender and weak; and by these it will overtop bushes, trees, &c. twenty or thirty feet high.

6. Bignonia grandiflora. This is also a shrubby climbing plant, a native of Japan. The flowers are purple, and as large as a rose.

The cultivation of the bignonia is not difficult. If the shoots are laid upon the ground, and covered with a little mould, they will immediately strike root, and become good plants for setting out where they are wanted, or they will all grow by cuttings. As to the catalpa, whoever has the conveniency of a bark bed may propagate it in plenty by cuttings: which being planted in pots, and plunged into the beds in the spring, will soon strike root; and may afterward be so hardened to the open air, that they may be set abroad in the shade before the end of summer: in the beginning of October they should be removed into a green house, or under some shelter, to be protected from the winter's frost. In the spring, after the bad weather is past, they may be turned out of the pots, and planted in the nursery way, in a well sheltered place; and if the soil be rich, and rather moist, it will be the better.

BILANCIIS *deferendis*, in law, a writ directed to a corporation for carrying weights to a haven, there to weigh wool, that persons were formerly licensed to transport.

BILANDER, a small flat bottomed vessel, with only one large mast and sail, and its deck raised half a foot above the platboard.

BILBOWS, a punishment at sea, answering to the stocks on land. The offender is laid in irons, or stocks, which are more or less ponderous according to the quality of the offence of which he is guilty.

BILGE, of a ship, the bottom of her floor, or the breadth of the place the ship rests on when she is aground. Therefore bilge water is that which lies on her floor, and cannot go to the well of the pump; and bilge pumps, or burr pumps, are those that carry off the bilge water. They likewise say the ship is bilged, when she has some of her timber struck off on a rock or anchor, and springs a leak.

BILE, a yellow, bitter juice, separated from the blood in the liver, collected in the porus biliarius and gall bladder, and thence discharged by the common duct into the duodenum. See Physiology, and Chymistry.

BILIOUS *fevers* are those occasioned by the over copiousness, or bad qualities, of the bile. See Medicine.

BILL, an instrument made of iron, edged in the form of a crescent, and adapted to a handle. It is used by plumbers to perform several parts of their work; by basket makers, to cut the largest pieces of chesnut trees and other wood; and by gardeners to prune trees. When short, it is called a hand bill; and when long a hedge bill.

BILL, in law proceedings, is a declaration in writing, expressing either the wrong the complainant had suffered by the party complained of, or some fault committed against some law or statute of the realm; and this bill is sometimes addressed to the lord chancellor, especially for unconscionable wrongs done to the complainant; and sometimes to others having jurisdiction, according as the law directs. It contains the fact complained of, the damages thereby sustained, and petition of process against the defendant for redress; and it is made use of in criminal as well as civil matters. In criminal cases, when a grand jury upon presentment, or indictment, finds the same to be true, they indorse on it *billa vera*, and thereupon the offender is said to stand indicted.

Many of the proceedings in the king's bench are *by bill*, which was the ancient form of proceeding.

Bill *of credit*, is that which a merchant or banker gives to a person whom he can trust, empowering him to receive money from his correspondents in foreign countries. Though bills of credit are different from bills of exchange, yet they enjoy the same privileges: for the money paid in consequence of them is recoverable by law.

Bill *in equity*, is in the form of a petition, addressed to the lord chancellor or barons of the exchequer, with which a suit in chancery, or the exchequer commences, and which sets forth the circumstances of the case at length.

Bills *of exchange*. A bill of exchange is an order or request in writing, addressed by one person to another, to pay a certain sum of money on demand, or at a time specified, to a third person, or to his order; or it may be made payable to bearer.

If a bill is made payable to bearer, it is assignable by delivery only; but if it is payable to order, it must be transferred by indorsement and delivery. The person making or drawing the bill is called the *drawer;* the person to whom it is addressed the *drawee;* who, when he has undertaken to pay the amount, is termed the *acceptor*. The person in whose favour the bill is drawn is called the *payee;* but if he appoints some other person to receive the money, he is then termed the *indorser*, and the person so appointed the *indorsee*. No particular form is necessary in a bill of exchange; any order, or promise, which from the time of making it, cannot be complied with, or performed, without *the payment of money*, is a bill or note. Mod. 364.

A promissory note, or note of hand, is an engagement in writing, to pay a sum specified at the time therein limited, to a person, therein named, or sometimes to his order, or often to the bearer at large: this is also made assignable, and indorsable like a bill of exchange. Any persons capable of binding themselves by a contract may be parties to a bill of exchange, or other negotiable instrument, or be in any manner concerned in negotiating either of them. An infant, therefore, or a married woman, except in certain cases, as where by the custom of London she has the privilege of trading as a *feme sole*, as they are incapable

of binding themselves by contract, cannot be parties to a negotiable instrument; yet such instrument, negotiated by persons incapacitated, will nevertheless *be valid* as to all other *competent* parties. 2 Atk. 181.

Bills of exchange are either *foreign* or *inland: foreign* when drawn by a merchant residing abroad upon his correspondent in England, or *vice versa;* and *inland*, when both the drawer and the drawee reside in the kingdom. By 9 and 10 W. III. c. 17. and 3 and 4 Anne, c. 9. all distinctions between foreign and inland bills, as far as respect the custom of merchants, are removed; and the same principles of law are generally applicable to both. See STAMPS.

Bills or notes must be certain, and not depend on any particular event or contingency. 3 Wils. 213.

If a bill or note is made in a foreign country, it must be conformable to the laws of that country, or it will not be valid.

If a bill or note is altered while in the hands of the *payee*, or *any other* holder, in any material instance, as date, sum, &c. without consent of the *drawee*, he will be discharged from his liability, although such bill or note may afterward come into the hands of an *indorsee* not aware of the alteration; but in this case, if altered *before* acceptance or indorsement, the *acceptor* can take no advantage of the alteration; and the *consent* of any one of the parties to the alteration, will in general preclude him from taking an advantage of it. 4 T. R. 320.

If a bill is made with a proper stamp, and afterward altered by the consent of the parties, though before negotiation; a new stamp is necessary, as it is a different contract. 5 T. R. 357. If, however, there be a stamp of equal or superior value, the proper one may be affixed, on payment of 40*s.* *before* the instrument is due, and 10*l.* *after* it is due. But if there is not originally a stamp amounting to the requisite value, *the omission* can never be legally supplied. Evans, p. 6.

The acceptor of a bill is, by the custom of the merchants, as effectually bound by his acceptance, as if he had been the original drawer; and having once accepted it, he cannot afterward revoke it. Cro. Jac. 303. See ACCEPTANCE. The indorser of a bill is as liable as the first drawer; because the indorsement is in the nature of a new bill. 1 Salk. 125. To indorse a bill with a fictitious name, is forgery, though such indorsement be useless.

A *presentment*, either for payment or acceptance, must be made at seasonable hours. In case a bill is not regularly paid, the holder has a right to recover not only the principal, but also, in certain cases, costs and damages.

Notice is that information which the holder of a negotiable instrument is bound to give to all the antecedent parties. If the drawee refuses to accept, or having accepted, if he refuses payment, or if he offers an acceptance varying from the bill; in either of the above cases, the bill is dishonoured; and the holder, in case of neglect to communicate notice within a reasonable time, will not be at liberty to resort to the other parties, who by such negligence will be discharged from their respective obligations. Bur. 2670. Notice of conditional or partial acceptance should be given to the other parties to the bill by the holder, in default of payment; for if under these circumstances a general notice of non-acceptance is given to any of the parties, omitting to mention in such notice the nature of the acceptance offered, the acceptor is discharged, by this act of the holder, from his acceptance. 1 T. R. 182.

A *protest* is an act of a notary public, stating that a bill has been presented for acceptance, or for payment, and refused, and declaring that the acceptor, indorsers, &c. shall be liable for damages, &c. and to this instrument all foreign courts give entire credit. In the first instance the notary marks or notes the minute of refusal on the bill itself, and afterward the instrument is drawn out and attested under his hand and seal. The want of a protest can in no case be supplied by noting, which is a mere preparatory minute, of which the law takes no cognisance as distinguished from a protest. If there is no notary resident at or near the place, the bill must, when payable, be protested by some substantial resident, in the presence of two or more witnesses, and should in general be made at the place where payment is refused; but when a bill is drawn abroad, directed to the drawee at Southampton or London, or any other place, requesting him to pay the payee in London, the protest for non-acceptance of such bill may be made either at Southampton or London. Notice should be given on the day of refusal to accept, if any post or ordinary conveyance set out on the day; and if not, by the next earliest conveyance. 4 T. R. 174.

An *usance* is generally understood to mean only a month. Molloy 207. 1 Shaw 217. Instead of an express limitation by months or days, we continually find the bills drawn or payable at Amsterdam, Rotterdam, Hamburgh, Altona, Paris, or any other place in France, Cadiz, Madrid, Bilboa, Leghorn, Genoa or Venice, limited by the usance, that is, the usage between those places and this country. An usance between this kingdom and Amsterdam, Rotterdam, Hamburgh, Altona, Paris, or any place in France, is one calendar month from the date of the bill; an usance between us and Cadiz, Madrid, or Bilboa, two; an usance between us and Leghorn, Genoa, or Venice, three. A double usance is double the accustomed time; a half usance, half. Upon a half usance, if it be necessary to divide a month, the division, notwithstanding the difference of the length of months, shall contain fifteen days. Blag. 13.

BILL *of entry*, an account of the goods entered at the custom houses both inward and outward. In this bill must be expressed the merchant exporting or importing the quantity of merchandises, and the divers species thereof, and whither or whence transported.

BILL *of lading*, an acknowledgment signed by the master of a ship, and given to a merchant, &c. containing an account of the goods which the master has received on board from that merchant, &c. with a promise to deliver them at an intended place for a certain sum. Each bill of lading must be treble: one for the merchant who loads the goods, another to be sent to the person to whom they are consigned, and the third to remain in the hands of the master of the ship. It must be observed, however, that a bill of lading is used only when the goods sent on board a ship are but part of the cargo: for when a merchant loads a whole vessel for his own personal account, the deed passed between him and the master of the ship is called charter party.

Bill *in parliament*, a paper containing propositions offered to the houses, to be passed by them, and then to be presented to the king to pass into an act or law.

Bill *of sale*, is when a person wanting a sum of money, delivers goods as a security to the lender, to whom he gives this bill, empowering him to sell the goods in case the sum borrowed is not repaid, with interest, at the appointed time.

Bill *of store*, a license granted at the custom house to merchants, by which they have liberty to carry, custom free, all such stores and provisions as they may have occasion for during their voyage.

Bill *of sufferance*, a license granted to a merchant, at the custom house, suffering him to trade from one English port to another, without paying custom.

Bill, or *beak*, the elongated horny processes or mandibles of birds. The form of the bill varies so greatly in different kinds of birds, that they afford the most permanent character by which these creatures may be arranged. In the distribution of families, Linnæus first notices the structure of the bill, the tongue, and nostrils, and these parts constitute almost exclusively, with the legs, the distinction of the genera likewise. The phœnicopter's bill is a true hyperbole: the upper part moves and the lower is fixed, which is the contrary to what is found in other kinds. The woodpecker's bill will pierce the hardest timber. In the island of Ferro, a fixed reward is given for the bills of ravenous birds. All watermen are obliged to bring a certain number yearly to the country courts, at the feast of St. Olaus, when they are thrown into a heap and burnt in triumph.

BILLET, in heraldry, a bearing in form of a long square. They are supposed to represent pieces of cloth of gold or silver, but Guillim thinks they represent a letter sealed up; and other authors take them for bricks. Billeté signifies that the escutcheon is all over strewed with billets, the number not ascertained.

BILLIARDS, an ingenious kind of game played on an oblong table, covered with green cloth, and placed exactly level, with little ivory balls, which are driven by crooked sticks, made on purpose, into hazards or holes on the edge and corners of the table, according to certain rules of the game.

BIMEDIAL, in mathematics. If two medial lines, as A B and B C, commensurable only in power, containing a rational rectangle, are compounded, the whole line A C will be irrational, and is called a first bimedial line.

See Euclid, lib. X. prop. 38.

BINARY arithmetic, that wherein unity or 1 and 0 are only used.

This was the invention of Mr. Leibnitz, who shows it to be very expeditious in discovering the properties of numbers, and in constructing tables: and M. Dangecourt, in the History of the Royal Academy of Sciences, gives a specimen of it concerning arithmetical progressionals; where he shows that, because in binary arithmetic, only two characters are used, therefore the laws of progression may be more easily discovered by it than by common arithmetic.

All the characters used in binary arithmetic, are 0 and 1; and the cypher multiplies every thing by 2, as in the common arithmetic by 10. Thus 1 is one, 10, two; 11, three; 100, four; 101, five; 110, six; 111, seven; 1000, eight; 1001, nine; 1010, ten; which is built on the same principles with common arithmetic.

The author, however, does not recommend this method for common use, because of the great number of figures required to express a number; and adds, that if the common progression were from 12 to 12, or from 16 to 16, it would be still more expeditious.

Binary arithmetic appears to have been the same with that used among the Chinese 4000 years ago, and left in enigma by Fohi, the founder of their empire and sciences.

Binary measure, in music, is a measure which is beaten equally, or where the time of rising is equal to that of falling. This is usually called common time, besides which there is a binary triple.

BIND of eels, a quantity consisting of two hundred and fifty; or ten strikes, each containing twenty-five eels.

Bind weed. See Convolvulus.

BING, in the alum works, denotes a heap of alum thrown together in order to drain.

BINOMIAL, in algebra, a root consisting of two members connected by the sign + or —. Thus $a + b$ and $8 - 3$ are binomials, consisting of the sum and difference of these quantities.

The powers of any binomial are found by a continual multiplication of it by itself. For example, the cube or third power of $a + b$, will be found by multiplication to be $a^3 + 3a^2b + 3ab^2 + b^3$; and if the powers of $a - b$ are required, they will be found the same as the preceding, only the terms in which the exponent of b is an odd number will be found negative. Thus, the cube of $a - b$ will be found to be $a^3 - 3a^2b + 3ab^2 - b^3$; where the second and fourth terms are negative, the exponent of b being an odd number of these terms. In general, the terms of any power of $a - b$ are positive and negative by turns. See Algebra.

BINOCULAR telescope, a kind of dioptric telescope fitted with two tubes joined in such a manner, that one may see a distant object with both eyes at the same time.

BIPED, an animal furnished with only two legs. Men and birds are bipeds. Apes occasionally walk on their hind legs, and seem to be of this tribe; but their more natural position is on all four.

The term is used for a genus of reptiles that belong to the lizard family. These have a very long body covered with scales, and the toes of the two little feet are armed with nails.

BIPENNIS, in Roman antiquity, an ax with a double edge, one of which was used in stabbing, and the other in cutting.

BIQUADRATIC power, in algebra, the fourth power, or squared square, of a number; as 16 is the biquadratic power of 2; for 2×2 is 4, and 4×4 is equal to 16.

Biquadratic root of a number, is the square root of its square root; thus the biquadratic root of 81 is 3; for the square root of 81 is 9, and the square root of 9 is 3. See Algebra.

Biquadratic equation, an equation where the unknown quantity of one of the terms has four dimensions.

Any biquadratic equation may be conceived as generated by the multiplication of four simple equations. Thus, if $x = a$, $x = b$, $x = c$, $x = d$, or $x - a = 0$, $x - b = 0$, $x - c = 0$, $x - d = 0$; then will $x - a \times x - b \times x$

$-c \times x - d = 0$ beget a biquadratic equation. Or it may be formed of two quadratic equations, as $x^2 + bx + c \times x^2 + dx + e = 0$; or, lastly, it may be produced from the multiplication of one cubic and one simple equation, as $x - a \times x^3 + cx^2 + dx + e = 0$.

BIRCH TREE. See BETULA.

BIRD, avis, in zoology, one of the six general classes of animals, the characters of which are, that their body is covered with feathers, and that they have two wings, two legs, and a bill of a firm bony, or rather horny substance: add to this, that the females are all oviparous.

The knowledge of birds, of the orders and genera into which they are subdivided, and of their nature, uses, figures, &c. constitutes a particular science, under the name of ornithology; in which there are six orders, *viz.* accipitres, picæ, anseres, grallæ, gallinæ, and passeres.

BIRDS, in heraldry, according to their several kinds, represent either the contemplative or active life. They are the emblems of liberty, expedition, readiness, swiftness, and fear. Birds that are either whole footed, or have their feet divided and yet have no talons, are said to be membered; but the cock, and all birds of prey with sharp and hooked beaks and talons, for encounter or defence, are termed armed. In the blazoning of birds, if their wings are not displayed, they are said to be borne close; as, he beareth an eagle, &c. close.

BIRD CATCHING, is the art of taking birds or wild fowl, either for food, or for the pleasure of their songs in cages, or for preventing the destruction which some species of them occasion to the husbandmen. Some recur to it as an amusing pastime, and others practise it as a profitable employment. There are various methods of catching birds: one of the most systematic and ingenious is practised in the neighbourhood of London, by persons who find a ready market for birds of any kind, which at certain seasons of the year change their situation, and hence are called birds of flight. The birds usually taken on such occasions, are woodlarks, titlarks, linnets, goldfinches, greenfinches, &c. which are taken during what is called their flight, or while they congregate for the purpose of propagating their species. The nets used by bird catchers are about twelve yards long, and two and a half wide; which are spread on the ground parallel to one another, and at such a distance, that when turned over, they shall coincide. The remaining apparatus consist of lines so fastened to the nets, that the bird catcher is able by a sudden pull to draw the net over the birds that may have alighted in the space between the parallel sides. These birds are enticed to alight by others usually denominated call birds, of which there are generally five or six linnets, two goldfinches, two greenfinches, one woodlark, one redpoll, a yellowhammer, a titlark, an aberdavine, and perhaps a bullfinch. Besides these, they have others which are called flur birds: but the call birds are particularly trained for the service; and when the nets are laid, these are properly arranged, and they appear to possess a most malicious desire of bringing the wild ones into the same state of captivity with themselves. When they perceive the approach of the wild birds, the intelligence is announced from cage to cage with the utmost ectasy. The note by which they invite them down, has so powerful an ascendancy over the wild birds, that the moment they hear it, they alight on a spot within twenty yards of the bird catchers. If only half the flock is caught by the first pull of the string, the others that escape will soon return to the net, and share the fate of their companions: such is the fascinating power that the call birds possess over those that are wild.

Birds are caught in traps of various kinds; and frequently by nooses of hair. In this way, great numbers of wheatears are annually taken on the various downs of England. Small holes are dug by the shepherds in the ground, in each of which is placed a noose. Whenever a cloud obscures the sun, these timid birds seek for shelter under a stone, or creep into any holes that present themselves; and they are thus insnared by the nooses which fasten around their necks. Woodcocks and snipes are taken likewise by nooses of horse hair placed along their paths, in marshes and moist grounds. Wild ducks in all their varieties are taken in vast numbers every winter on our coasts by means of decoys. See DECOY. Grouse and partridges are taken by means of nets; either at night when resting on the ground, by observing where they alight, and when setted, drawing a net over that part of the field; or, in the day, a very steady dog is used to point at them. The attention of the birds being thus fixed, two persons, drawing the two extremities of a large net, pass it over them, and thus secure a whole pack of grouse, or covey of partridges, at once. Pheasants are sometimes taken by night, by holding flaming sulphur under the trees on which they are observed to perch, the suffocating effluvia of which make them fall senseless.

In various parts of the world, peculiar modes are adopted for insnaring and taking birds; some of which, whilst they are hazardous to those who practise them, excite no inconsiderable degree of surprise, and even of anxiety, in the spectators. Thus, in the Orkney islands, where the birds that inhabit the rocks, and the eggs which they deposite among the cliffs, supply the principal food of many among the poorer inhabitants, the intrepid and adventurous fowlers climb rocky precipices more than fifty fathoms above the sea, and pass from one shelf or ledge to another, whose breadth is barely sufficient for resting places to the birds which deposite their eggs upon them. In this hazardous employment, the adventurers are commonly lowered from above by means of a rope, formed often of brittle materials, and held by a single assistant. Fastened to this rope, the intrepid peasant descends, and searches all the cavities for eggs; springing from one projecting ledge to another, by the help of a pole: whilst the assistant, upon receiving the necessary signals, shifts the rope from one part of the rocky precipice to another. If the weight of the fowler and of his booty should, in these perilous circumstances, overpower his associate above, or the craggy rock cut the rope, inevitable destruction must await the adventurer; for he will either be dashed against the projecting rock, or drowned in the subjacent sea. But the most singular mode of bird catching is in the holm of Noss; which is a huge rock severed from the isle of Noss by some unknown convulsion, and distant from it about sixteen fathoms. The opposite cliffs are separated by the raging sea. The adventurer, having reached the rock in a boat, and ascended to the top of it, fastens several stakes in the shallow soil that is found on the surface of the rock; and similar stakes are also attached to the edge

of the corresponding and opposite cliff. A rope is then fixed to the stakes on both sides, upon which a machine, called a cradle, is contrived to slide; and by the help of a small parallel cord fastened in like manner, the daring adventurer wafts himself over, and returns with his booty.

In the Feroe islands the method of bird catching is more extraordinary and hazardous than any which has already been recited. The cliffs to which the fowlers recur, are in many cases 200 fathoms high; and they are traversed both from above and below. In the first case, the fowlers provide themselves with a rope 80 or 100 fathoms long; and the adventurer fastens one end about his waist and between his legs, and having recommended himself to the protection of the Almighty, he is lowered down by six associates, who place a piece of wood in the margin of the rock, that the rope may be preserved from being fretted and broken by its sharp edge. To his body is fastened a small line, which serves for enabling him to give the necessary signals, when he wishes to be raised or lowered, or shifted from one place to another. In changing his situation he is exposed to the hazard of injury from loosened and falling stones; which falling on the head, must inevitably destroy him, if he was not in some degree protected by a strong thick cap. The fowlers, by their astonishing dexterity, contrive to place their feet against the front of the precipice, and to dart themselves some fathoms from it, for the purpose of surveying the roosting places of the birds, and projecting themselves into the deep recesses where they lodge. There the fowler alights: and disengaging himself from the rope, which he fixes to a stone, collects the booty at his leisure, attaches it to his girdle, and when this is done, resumes his suspended posture. He will also, when occasions require it, spring from the rock; and in this attitude, by means of a fowling net fixed to the end of a staff, catch the old birds which are flying to and from their retreats. When this hazardous operation is finished, he gives a signal to his companions above; who pull him up, and divide the booty. The feathers are preserved for exportation; the flesh is partly eaten fresh, and the greater part is dried for winter's provision. In fowling from below, the party have recourse to a boat; and when they have arrived at the base of the precipice, one of the most intrepid of them fastens a rope about his waist, and being furnished with a long pole, with an iron hook at one end, either climbs, or is thrust up by his companions, who place a pole under him, to the next footing spot within his reach. By means of the rope he hoists up one of the boat's crew; and the rest are drawn up in the same manner, each of them being furnished with his rope and fowling staff. They then pursue their journey upward, till they arrive at the region of the birds; and they wander about the cliff in search of them. They next act in pairs; one fastens himself to the end of his associate's rope, and, in places where birds have nestled beneath his footing, he suffers himself to be lowered down, depending for safety on the strength of his companion, by whom he is again hauled up; but it sometimes happens that the person above is overpowered by the weight, and in this case both inevitably perish. The fowl is flung into the boat, which attends their operations for the purpose of receiving the booty. The fowlers often pass seven or eight days in this perilous occupation, and lodge in the crannies which they find in various parts of the precipice.

BIRDLIME, a viscid substance, prepared in different ways. The most common birdlime among us is made from holly bark, boiled ten or twelve hours; when the green coat being separated from the other, it is covered up a fortnight in a moist place, then pounded into a tough paste so that no fibres of the wood are discernible, and washed in a running stream till no motes appear; put up to ferment four or five days, skimmed as often as any thing arises, and laid up for use. To use it, a third part of nut oil, or thin grease, must be incorporated with it over the fire. It is also made from the gluten of wheat.

The Italians make birdlime of the berries of the misleto tree. That which comes from Damascus is supposed to be made of sebastens: and it is said that the bark of any of our wayfaring shrubs will make very good birdlime.

BIRRUS, in Roman antiquity, a cloak made of woollen cloth, worn by the soldiers: also a robe worn by the priests or bishops.

BIRTH. See MIDWIFERY.

BIRTH, or BIRTHING, in the sea language, a convenient place to moor a ship in; also a due distance observed by ships lying at anchor, or under sail; and a proper place aboard for a mess to put their chests, &c. is called the birth of that mess.

BIRTHWORT. See ARISTOLOCHIA.

BISA, or BIZA, a coin of Pegu, which is current there for half a ducat. It is also a weight used in that kingdom.

BISCUTELLA, BUCKLER MUSTARD, or bastard Mithridate mustard; a genus of the tetradynamia siliculosa class and order of plants; and in the natural method ranking under the 39th order, siliquosæ. The silicula is flat compressed, rounded above, and below two lobed, and the leaves of the calyx are gibbous at the base. There are six species, all natives of France, Italy, Spain, and Germany; of which the most remarkable are:

1. Biscutella apula, with flowers growing in spikes, and a shorter style.

2. Biscutella auriculata, with small pods joined to the style.

3. Biscutella didyma, with a double orbicular pod diverging from the style.

BISECT, to divide into two parts. The rational horizon bisects the globe into two equal parts.

BISELLIARI, or BISELLIARII, in antiquity, those who enjoyed the honour or privilege of the bisellium.

BISELLIUM, in antiquity, a kind of seat or chair, larger and richer than ordinary, big enough to hold two persons, wherein to sit in courts, theatres, and other public assemblies.

BISERRULA, a genus of the decandria order, and diadelphia class of plants; and in the natural method ranking under the 32d order, papilionaceæ: the legumen is biloccular and flat; and the partition contrary. Of this genus there is only one species known, *viz.*

Biserrula pelecina, an annual plant, with purple flowers; a native of the south of Europe.

BISHOP, signifies an overseer or superintendant. An archbishop, is the chief of the clergy in his own province, who next and immediately under the king has supreme power, &c. in all causes and things ecclesiastical; and has the inspection of all the bishops of that province. He has also his own diocese, where he exercises episcopal jurisdiction, as in his province he exercises archiepiscopal.

As archbishop, upon receipt of the king's writ, he calls the bishops and clergy of his province to meet in convocation: to him all appeals are made from inferior jurisdictions within his province. During the vacancy of any see in his province, he is guardian of the spiritualities thereof. If the archiepiscopal see is vacant, the dean and chapter are the spiritual guardians. The archbishop is entitled to present by lapse, to all the ecclesiastical livings in the disposal of the diocesan bishops, if not filled within six months. And he has a customary prerogative, when a bishop is consecrated by him, to have the next presentation to such dignity or benefice in the bishop's disposal, as the archbishop shall choose; which is therefore called his option, 1 Blacks. 380. The archbishops may retain and qualify eight chaplains, whereas a bishop can only qualify six.

Bishops are elected by the dean and chapter; in order whereunto, when a bishop dies or is translated, the dean and chapter certify the king thereof in chancery; upon which the king issues a license to them to proceed to an election, called a congé-d'elire: and with it sends a letter missive, containing the name of the person whom they shall elect; which if they shall refuse to do, they incur the penalty of a præmunire.

A bishop must be full thirty years of age when consecrated.

A bishop has his consistory court, to hear ecclesiastical causes; and is to visit the clergy, &c. He consecrates churches; ordains, admits, and institutes priests; confirms, suspends, excommunicates, grants licenses for marriage, makes probates of wills, &c. Co. Lit. 96. Rol. Abr. 230.

In England there are twenty-four bishopricks, and two archbishopricks; in Scotland, none; in Ireland eighteen bishopricks, and four archbishopricks: and in the popish countries abroad they are still more numerous.

All bishops of England are lords of parliament, except the bishop of Man, and as such sit and vote in the house of lords; they are barons in a threefold manner, *viz.* feudal, in regard to the temporalities annexed to their bishopricks; by writ, as being summoned by writ to parliament; and lastly, by patent and creation: accordingly, they have the precedence of all other barons, and vote as barons and bishops, and claim all the privileges enjoyed by the temporal lords, excepting that they cannot be tried by their peers; because, in cases of blood, they themselves cannot pass upon the trial, for they are prohibited by the canons of the church, to be judges of life and death.

BISKET. See Baker.

BISMILLAH, a solemn form used by the Mahometans, at the beginning of all their books and other writings, signifying "in the name of the most merciful God."

It is also used among the Arabs as a word of invitation to eat. An Arab prince frequently sits down to eat in the street before his own door, or under the shade of a wide spreading tree, and calls all that pass, even beggars, by this word, who come and sit down to eat with him; "for," says Pococke, "the Arabs are great levellers, and set every body on a footing with themselves."

BISMUTH, in natural history, a genus of the semimetals, the most usual appearance of which is in form of an ore, intimately mixed with silver, a large quantity of arsenic, and an earthy matter which yields cobalt.

The ancients were acquainted with bismuth, but they confounded it with tin. It is mentioned occasionally by the alchymists and earlier mineralogists; and referred sometimes to tin, sometimes to lead, and sometimes to antimony. The German miners gave it the name of lectum argenti; and appear to have considered it as silver beginning to form, and not yet completed.

Bismuth is of a reddish white colour, and almost destitute of taste and smell. It is composed of broad brilliant plates adhering to each other. The figure of its particles, according to Hauy, is an octahedron, or two four sided pyramids applied base to base.

Its hardness is 7. Its specific gravity is 9.8227.

When hammered cautiously, its density, as Muschenbroek ascertained, is considerably increased. It is not therefore very brittle; it breaks, however, when struck smartly by a hammer, and consequently is not malleable. Neither can it be drawn out into wire. Its tenacity has not been ascertained.

When heated to the temperature of 4600, it melts; and if the heat is much increased, it evaporates, and may be distilled over in close vessels. When allowed to cool slowly, and when the liquid metal is withdrawn, as soon as the surface congeals it crystalizes in parallelopipeds, which cross each other at right angles.

When exposed to the air, it soon loses its lustre, but scarcely undergoes any other change. It is not altered when kept under water.

Only two oxides of bismuth are at present known. But the combination of this metal with oxygen has been more neglected by chymists than almost any other.

When kept melted in an open vessel, its surface is soon covered with a dark blue pellicle; when this is removed, another succeeds, till the whole metal is oxidized. When these pellicles are kept hot and agitated in an open vessel, they are soon converted into a brownish powder, known by the name of brown oxide. This is the protoxide of bismuth. According to Fourcroy, it is composed of ninety parts of bismuth, and ten of oxygen.

When bismuth is raised to a strong red heat, it takes fire, and burns with a faint blue flame, and emits a yellow smoke. When this is collected, it is a yellow powder, not volatile, which has been called yellow oxide of bismuth.

When bismuth is dissolved in nitric acid, if water is poured into the solution, a white powder precipitates, which was formerly called magistery of bismuth, and at present white oxide of bismuth. According to the experiments of Klaproth, it is composed of 81.3 parts bismuth and 17.7 of oxygen. This oxide is used as a paint under the name of pearl white.

The oxides of bismuth are very easily converted into glass; for that reason bismuth is sometimes used in the process of cupellation instead of lead. It was first proposed for that purpose by Dufay, in 1727, and his experiments were afterward confirmed by Pott.

These oxides are easily reduced when heated with charcoal or other combustible bodies; for the affinity between bismuth and oxygen is but weak.

Bismuth has not been combined with carbon or hydrogen, neither does it seem capable of combining in any notable proportion with phosphorus.

Sulphur combines readily with bismuth by fusion. The sulphuret of bismuth is of a bluish gray colour, and crystalizes into beautiful tetrahedral needles. It is composed of 85 parts of bismuth and 15 of sulphur.

Bismuth combines with almost all the metals, but few of its alloys are much used. 1. Equal parts of bismuth and gold form a brittle alloy, nearly of the same colour with bismuth; the specific gravity of which is greater than the mean. 2. The alloy of bismuth and platinum is also very brittle. When exposed to the air, it assumes a purple, violet, or blue colour. The bismuth can scarcely be separated by heat. 3. Bismuth combines readily with silver by fusion. The alloy is brittle, lamellar, and nearly of the colour of bismuth. This alloy is sometimes formed, in order to purify silver by the process of cupellation. 4. Mercury combines readily with bismuth, either by triturating the metals together, or by pouring two parts of hot mercury into one part of melted bismuth. This amalgam is at first soft, but it becomes gradually hard. When melted and cooled slowly, it crystalizes. When the quantity of mercury exceeds the bismuth considerably, the amalgam remains fluid, and has the property of dissolving lead and rendering it also fluid. This triple compound may be filtered through shamoy leather without decomposition. Mercury is sometimes adulterated with these metals; but the imposition may be easily detected, not only by the specific gravity of the mercury, which is too small, but because it drags a tail, as the workmen say; that is, when a drop of it is agitated on a plane surface, the drop does not remain spherical, but part of it adheres to the surface, as if it was not completely fluid, or as if it was enclosed in a thin pellicle. 5. Copper forms with bismuth a brittle alloy of a pale red colour, and the specific gravity exactly the mean of that of the two metals alloyed. 6. Bismuth combines but imperfectly with iron. The alloy is brittle, and attracted by the magnet even when the bismuth amounts to three fourths of the whole. The specific gravity of this alloy is less than the mean. 7. Bismuth and tin unite readily. A small portion of bismuth increases the brightness, hardness, and sonorousness of tin: it often enters into the composition of pewter. Equal parts of tin and bismuth form an alloy that melts at 280 degrees; eight parts of tin and one of bismuth melt at 390 degrees; two parts of tin and one of bismuth at 330 degrees. 8. The alloy of lead and bismuth is of a dark gray colour, and close grain. It is ductile, unless the bismuth exceeds the lead considerably. Bismuth increases the tenacity of lead prodigiously. Muschenbroek found, that the tenacity of an alloy composed of three parts of lead and two of bismuth was ten times greater than that of pure lead. The specific gravity of this alloy is greater than the mean. 9. When eight parts of bismuth, five of lead, and three of tin, are melted together, a white coloured alloy is obtained, which melts at the temperature of 212 degrees, and therefore remains fusible under boiling water. 10. The alloy of bismuth is brittle, and formed of thin plates. 11. Bismuth does not combine with zinc.

BISON. See Bos.

BISSECTION, in geometry, the division of a line, angle, &c. into two equal parts.

BISSEXTILE, in chronology, a year consisting of three hundred and sixty-six days, being the same with our leap year.

The true solar year, or that space of time which flows while the sun is moving from any one point of the ecliptic till he returns to the same point again, consists of 365 days, 5 hours, 48 minutes, 57 seconds. The year made use of by the ancient Egyptians consisted of 365 days; which being less than the true solar year by nearly six hours, they lost a day every four years. Julius Cæsar being high priest among the Romans, and considering the inconveniencies arising from this method of computation, ordered that every fourth year should have an intercalary day, and that this additional day should be added to the month of February; wherefore this method of computation is called the Julian account, or old style.

Yet, as the true length of the year consists of 365 days, 5 hours, 49 minutes nearly, it follows that, according to this way of reckoning, at the end of every four years the civil year will begin 44 minutes sooner than it did before, consequently in 331 years it will anticipate by one whole day: for this reason pope Gregory XIII. set himself upon reforming the calendar; and finding, in the year 1582, that the equinox had anticipated ten whole days, he ordered that these ten days should be taken out of the calendar that year, and the 11th of March should be reckoned the 21st; and ordered that every hundredth year, which, according to the Julian form, was to be bissextile, should be a common year, and consist of 365 days: but because that was too much, every four hundredth year was to remain bissextile. This method of computation is called the Gregorian, or new style; it was received in most foreign countries ever since the reforming of the calendar; and by act of parliament passed in the twenty-fifth year of his late majesty's reign, *viz.* 1751, it commenced in all the dominions under the crown of Great Britain, in the year following; ordering that the natural day following the second of September, should be accounted the fourteenth, omitting the intermediate eleven days of the common calendar.

BISTI, in commerce, a small coin of Persia: some say that it is among the current silver coins of Persia, and worth only a little above three farthings of our money; others speak of it again as a money of account.

BISTORT. See Polygonum.

BISTOURY, in surgery, an instrument for making incisions, of which there are different kinds; some being of the form of a lancet, others straight and fixed in the handle like a knife, and others crooked with the sharp edge on the inside.

BISTRE, or Bister, among painters, denotes a glossy soot pulverized and made into a kind of cakes, with gum water. It is used to wash their designs.

Bistre is made by putting soot of dry wood, as beech, into water, in the proportion of two pounds to a gallon, and boiling them half an hour. After the fluid has settled, pour off the clearer part while it remains hot. Evaporate the fluid to dryness, and what remains is good bistre.

BIT, or Bitt, an essential part of a bridle. There are many kinds of bits; the most simple is a short rod of iron, made rather wider than the mouth of the horse, and provided with a hook or ring at each end for fastening the reins to. The next is a rod similar to the former, broken in two pieces, and connected by a joint in the middle; the former is intended for heavy draft horses, the latter for

those of light draft. The next is the snaffle, which is provided with two cross pieces that rest against the lips or sides of the mouth; for as the snaffle is intended for the saddle horse, and the reins go to the hands, so the cross pieces are useful in preventing the bit from being drawn through the mouth. The number of parts of which the mouthpiece of the snaffile is composed, may be increased to any extent, as it may be made with 1, 2, or several joints; and hence it acquires new properties and effects which require attention; its gentleness or rigour will depend almost wholly on these conditions. Another is the curb bit, the mouthpiece of which is usually provided with an upset or arch in the middle, as, if perfectly straight, it would rest upon the tongue, and occasion an unpleasant restraint. It has been sometimes called the liberty bit, on account of the freedom which it allows to the tongue; by others it has been called the porte mouth bit, vulgarly the Portsmouth bit; and by a supposed opposite expression we get the Weymouth bit.

Bit also denotes the iron part of a piercer, auger, and the like instruments.

Bit of a key, the part which contains the wards.

Bits, or Bitts, in ship building, the name of two great timbers usually placed abaft the manger, in the ship's loof, through which the cross piece goes; the use of it is to belay the cable thereto, while the ship is at anchor.

BITTACLE, on ship board, a square box standing before him that steers the ship, with the compass placed in it, to keep and direct the ship in her course.

BITTER, a sea term, signifying any turn of the cable about the bits, so as that the cable may be let out by little and little; and when a ship is stopped by a cable, she is said to be brought up by a bitter. Also that end of the cable which is wound about the bits is called the bitter end of the cable.

BITTERN, in the salt works, the brine remaining after the salt is concreted: this they ladle off, that the salt may be taken out of the pan, and afterward put in again; when, being further boiled, it yields more salt. See Salt.

BITUMEN, in natural history, is understood by mineralogists in general, to be an oil which is found in different parts of the earth, in various states of consistence. These different states form distinct species; in the arrangement of which we shall be guided by the observations which Mr. Hatchet has made in his valuable paper on bituminous substances.

Sp. 1. Naphtha. This substance is found sometimes on the surface of the water of springs, and sometimes issuing from certain strata. It is found in great abundance in Persia.

It is as fluid and transparent as water. Colour white, or yellowish white. Smell strong, but not disagreeable. Specific gravity when white .708 or .729; when yellowish .8475. Feels greasy. Catches fire on the approach of flame, burns with a white flame, and leaves scarcely any residuum.

Sp. 2. Petroleum. This substance is also found in Persia, and likewise in many countries in Europe, particularly Italy, France, Switzerland, Germany, Sweden, England, and Scotland. It is not so fluid or transparent as water. Colour yellow, either pale or with a shade of red or green; reddish brown, and reddish black. Smell that of naphtha, but less pleasant. Specific gravity .8783. When burnt it yields a soot, and leaves a small quantity of coaly residuum. By exposure to the air it becomes like tar, and is then called mineral tar.

Sp. 3. Mineral tar. This substance is found in many parts of Asia, America, and Europe. It is viscid, and of a black, brownish black, or reddish colour. Smell sometimes strong, but often faint. Specific gravity 1.1. When burned, emits a disagreeable bituminous smell. By exposure to the air it passes into mineral pitch and maltha.

Sp. 4. Mineral pitch and maltha. This substance has a strong resemblance to common pitch. When the weather is warm it is soft, and has some tenacity; it is then called adhesive mineral pitch: when the weather is cold it is brittle: its hardness is 5; and its fracture has a glassy lustre. In this state it is called maltha. Colour black, dark brown, or reddish. Opaque. Specific gravity from 1.45 to 2.07. Does not stain the fingers. On a white hot iron it flames with a strong smell, and leaves a quantity of gray ashes. It is to the presence of the earths which compose these ashes that the great specific gravity of this bitumen is to be ascribed. By further induration it passes into asphalt.

Sp. 5. Asphalt. This substance is found abundantly in many parts of Europe, Asia, and America, especially in the island of Trinidad.

Colour black, or brownish black. Lustre greasy, 2. Opaque. Fracture conchoidal, of a glassy lustre. Hardness from 7 to 8. Very brittle. Specific gravity 1.07 to 1.165. Feels smooth, but not greasy. Does not stain the fingers. Has little or no smell unless when rubbed or heated. When heated, melts, swells, and inflames; and when pure burns without leaving any ashes.

Sp. 6. Mineral caoutchouc. This substance was found about the year 1786 in the lead mine of Odin, near Castletown, Derbyshire. It was first mentioned by Mr. De Born.

Colour yellowish or reddish brown, sometimes blackish brown. In its appearance it has a strong resemblance to caoutchouc or Indian rubber; hence its name. Consistency various: sometimes so soft as to adhere to the fingers; sometimes nearly as hard as asphalt. When soft it is elastic; when hard, brittle. Specific gravity 0.9053 to 1.0233.

Insoluble in alcohol, ether, and oil of turpentine, but soluble in oil of olives. Not affected by nitric acid. When distilled it yields a bituminous oil insoluble in alcohol; the residuum is carbonaceous.

There is a variety of this substance found in a rivulet near the mine of Odin, which, when fresh cut, exactly resembles fine cork in colour and texture; but in a few days after being exposed to the air, becomes of a pale reddish brown. This substance contains within it a nucleus of elastic bitumen. It seems to be the elastic bitumen altered in its texture by the water.

BIVALVES, one of the three general classes of shell fish, comprehending all those, the shells of which are composed of two pieces, joined together by a hinge. The Linnæan genera of bivalve shells are mya solen, tellina, cardium, mactra, donax, venus, spondylus, chama, arca, astrea, anomia, mytillus, and pinna.

BIVENTER, in anatomy, a muscle of the lower jaw, that has its origin in the incisure under the mastoid process. See Ana.

BIXA, the roucou or anotto tree, a genus of the monogynia order, and polyandria class of plants; and in the natural method ranking under the 37th order, columniferæ. The corolla is ten petalled; the calyx quinquedented; the capsule hispid and bivalved. Of this genus there is but one species known, *viz.*

Bixa orellana, a native of the warm parts of America. It rises with an upright stem to the height of eight or ten feet, sending out many branches at the top forming a regular bed, with heart shaped leaves ending in a point, and having long footstalks. The flowers are produced in loose panicles at the end of the branches: these are of a pale peach colour, having large petals, and a great number of bristly stamina of the same colour in the centre. After the flower is past, the germen becomes a heart shaped, or rather a mitre shaped vessel, covered on the outside with bristles opening with two valves, and filled with angular seeds. These seeds are covered with a red waxen pulp or pellicle, from which the colour called anotta is prepared. These plants, in the countries where they grow, thrive best in a cool rich soil, and shoot most luxuriantly near springs and rivulets. With us, they may be propagated by seeds procured from America. These are to be sown in pots in the spring, and plunged in a bed of tanners' bark: the plants must afterward be removed into separate pots, and always kept in the stove.

BLACK, something opaque, and occasioned by the porosity of bodies, that imbibing the greater part of the light that falls on them, and reflecting little or none, exhibit no colour. Black bodies are more inflammable than others, because the rays of light falling on them are not reflected outward, but enter the bodies, and are lost in them. Being more porous, they are found cæteris paribus to be specifically lighter than any other coloured bodies.

The disposition of black bodies to acquire heat beyond those of other colours, has long been known. If a black and a white glove are worn by the same person in the sun, it will be found that the hand with the black glove will acquire the greatest degree of heat. Dr. Watson, the present bishop of Landaff, covered the bulb of a thermometer with a black coating of Indian ink, and the mercury presently rose ten degrees. Black clothes heat more, and dry sooner in the sun, than white clothes: black is therefore a bad colour for clothes in hot climates. Count Rumford has attempted to controvert this position, but his experiments do not appear decisive. See Philosophical Transactions for the year 1804.

Black, among dyers, one of the five simple and mother colours used in dying. See Dying.

Black, German, called by some Frankfort black, is made with the lees of wine, burnt, washed afterward in water, then ground in mills made for that purpose, with ivory, bones, or peach stones, also burnt. It comes from Frankfort, Mentz, and Strasbourg, either in lumps or powder; and must be chosen moist, without having been wetted, of a fine black, soft, friable, light, and with as few shining grains as possible. This black is the principal ingredient used by copperplate printers for working their engravings.

Black, ivory, otherwise called velvet black, is burnt ivory or bones, which, becoming quite black, and being reduced to thin plates, are ground in water, and made into troches, to be used by painters, and by jewellers, who set precious stones, to blacken the ground of the collets, and give the diamonds a teint or foil. In order to be good, it ought to be tender, friable, and thoroughly ground.

Black, hart's, that which remains in the retort after the spirits, volatile salt, and oil, have been extracted from hartshorn. It answers the purposes of painters almost as well as ivory black.

Black, Spanish, is nothing but burnt cork: it is used in several works. It should be light, and have as few grains of sand mixed with it as possible.

Black, lamp, originally, perhaps, the soot collected from lamps, is generally prepared by melting and purifying resin or pitch in iron vessels; then setting fire to it under a chimney, or other place made for the purpose, lined with sheepskins, &c. to receive the vapour or smoke; in this way vast quantities of it are prepared at Paris. In England it is prepared at the turpentine houses, from the dregs of the resinous matters which are manufactured there; but the greater part of lampblack is brought from Germany, Sweden, and Norway; where the process, in the preparation, is dependent on the manufacture of common resin.

The goodness of lampblack depends much on its lightness, and on the fulness of its colour. It is used on various occasions, particularly in printers' ink, for which it is mixed with oils of turpentine and linseed. A patent was taken out some years ago by Mr. Row, of Newcastle, for manufacturing lampblack from pit coal, or any kind of mineral and fossil coal, which we conceive must answer perfectly well.

Black, currier's. See Currier.

BLACKBIRD. See Turdus.

BLACKCAP. See Motacilla.

BLACKAMOOR'S *head*, in chymistry, consists of a conical vessel, surrounded with another of a cylindrical form, filled with cold water, with a cock to draw it off when it becomes too warm.

BLACK ACT, is so called, having been occasioned by some devastations committed near Watham in Hants, by persons in disguise, or with their faces blacked; to prevent which it is enacted by 31 Geo. II. c. 42. that persons hunting armed and disguised, and killing or stealing deer, or robbing warrens, or stealing fish out of any river, &c. or any person unlawfully hunting in his majesty's forests, or breaking down the head of any fish pond, or killing, &c. of cattle, or cutting down trees, or setting fire to house, barn, or wood, or shooting at any person, or sending anonymous letters, or signed with a fictitious name, demanding money, &c. or rescuing such offenders; are guilty of felony without benefit of clergy.

BLACK LEAD. Every person who shall unlawfully break into any wad hole of wad, or black cawke, commonly called black lead, or shall unlawfully take and carry away from thence any wad, black cawke, or black lead, or shall aid or employ others so to do, shall be guilty of felony. 25 Geo. II c. 10.

BLACK MAIL, signifies, in the counties of Cumberland, Northumberland, Westmoreland, and the bishoprick of Durham, a certain rate of money, corn, cattle, or other consideration, paid to some inhabitants near the bor-

ders, to be protected from a band of robbers called moss troopers.

Black mail, also signifies the rents formerly paid in provisions of corn and flesh.

BLACKBURNIA, a genus of the tetrandria monogynia class and order. The essential character is, calyx four toothed; pet. 4; anther heart shaped; germ. conic; stigma simple; berry one seeded. There is one species, a native of Norfolk island.

BLADDER, a thin membranous substance, found in several parts of an animal, serving as a receptacle of some juice, or of some liquid excrement, as the urinary bladder, gall bladder, &c. See Anatomy.

BLADHIA, a genus of the class and order pentandria monogynia. The essential character is, corolla wheel shaped, deciduous, berry containing one arilled seed. There are three species, natives of Japan.

BLÆRIA, in botany, a genus of the tetrandria monogynia class and order of plants. Its characters are; that the calyx is quadripartite, the corolla quadrifid, the stamina inserted in the receptacle; and the fruit a capsule, with four cells, containing many seeds. There are six species.

BLAFART, in commerce, a small coin current at Cologn, worth something more than a farthing of our money.

BLAIN, among farriers, a distemper incident to beasts; being a certain bladder growing on the root of the tongue, against the windpipe, which swells to such a degree as to stop the breath. It comes by great chafing and heating of the stomach; and is perceived by the beast's gaping and holding out his tongue, and foaming at the mouth: to cure it, cast the beast, take forth his tongue, and then slitting the bladder, wash it gently with vinegar and a little salt.

BLAKEA, in botany, a genus of the class and order dodecandria monogynia: with a calyx composed of six leaves below, and entire above; six petals, and a six celled polyspermous capsule. There are two species, very beautiful shrubs, natives of America and the West Indies.

BLANCHING of copper is done in various ways, so as to make it resemble silver. If it is done for sale, it is felony by 8 and 9 William III. ch. xxvi.

Blanching, in coinage, the operation performed on the planchets or pieces of silver, to give them the requisite lustre and brightness. They also blanch pieces of plate, when they would have them continue white, or have only some parts of them burnished.

Blanching, as it is now practised, is performed by heating the pieces on a kind of peel with a wood fire, in the manner of a reverberatory; so that the flame passes over the peel. The pieces, being sufficiently heated and cooled again, are put successively to boil in two pans, which are of copper: in these they put water, common salt, and tartar of Montpelier. When they have been well drained of this water in a copper sieve, they throw sand and fresh water over them; and when dry, they are well rubbed with towels.

Blanching also denotes the operation of covering iron plates with a thin coat or crust of tin.

BLANKET, a coverlet for a bed: a stuff commonly made of white wool, and wrought in a loom like cloth; with this difference, that they are crossed like serges. When they come from the loom, they are sent to the fuller; and after they have been fulled and well cleaned, they are napped with a fuller's teazle.

Blankets made of sheep's wool, are divided into several sorts; of the head and bay wool the widest are made; and narrow ones of the middling and common sort.

There are also blankets made with the hair of several animals; as that of goats, dogs, and others.

BLANQUILLE, in commerce, a small silver coin current in the kingdom of Morocco, and all that part of the coast of Barbary: it is worth about three half pence of our money.

BLASIA, leather cup, a genus of the order of algæ, and cryptogamia class of plants; and in the natural method ranking under the 57th order, algæ. The male calyx is cylindric, replete with grains; the female calyx is naked; the fruit roundish, immersed in the leaves, and many seeded. Of this genus there is but one species known, *viz.*

Blasia pusilla, which grows naturally on the banks of ditches and rivulets, in a gravelly or sandy soil, in England. It grows flat upon the ground in a patch, composed of numerous thin, green, pellucid leaves, marked with a few whitish veins near the base, divided and subdivided into obtuse segments obscurely crenated on the edges. The margins of the leaves are a little elevated, but the interior parts adhere close to the ground by a fine down which answers the purpose of roots. The seeds are so small as to be almost imperceptible.

BLASPHEMY: all blasphemies against God; all contumelious reproaches of Jesus Christ; all profane scoffing at the Holy Scriptures, or exposing any part of them to ridicule; are punishable by fine, imprisonment, and such corporal punishment as to the court shall seem meet, according to the heinousness of the crime. 1 Hew. 6.

BLAST, a disease in grain, trees, &c. The sugar cane in the West Indies is subject to a disease of this kind, which is thought to be occasioned by the aphis of Linnæus, which is distinguished into the black and yellow; of these, the latter is most destructive. It consists of myriads of insects, invisible to the naked eye, whose proper food is the juice of the cane, in search of which they wound the tender blades, and in the end destroy the vessels. It is said the blast never attacks those plantations where colonies have been introduced of the carnivorous ant, or formica omnivora. These minute and busy creatures soon clear a sugar plantation of rats; their natural food consists of all kinds of insects and animalcula.

Blast, a term used at iron founderies to denote the column of air introduced into the furnace for the purpose of combustion.

BLASTING, a term used by miners for the tearing up rocks which lie in their way, by the force of gunpowder.

In order to do this, a long hole is made in the rock, which being charged with gunpowder, they fill it up; leaving only a touch-hole, with a train or match to fire the charge.

BLATTA, a genus of the hymenopterous insects, called in England cockroaches, or vulgarly and erroneously, black beetles. The head is inflected; antennæ setaceous; feelers unequal and filiform; wings and wing cases smooth; the latter somewhat coriaceous; thorax flattish, orbicular, and margined; legs formed for running; abdomen terminating in two articulated appendages above the tail. In hotter climates the blatta are a very troublesome race: they enter houses and commit various depredations on the furniture, devour provisions of every kind, destroy clothes, and tor-

ment the inhabitants with their bite. The blatta most abundant in England was originally from the east, or as some imagine from America: it is now completely naturalized to our climate; and the best method of clearing houses of them, is to employ the agency of a tame hedgehog, who very soon devours them all.

All the known species of this insect, whether in the larva, pupa, or perfect winged state, secrete themselves in the day time, and wander about in the night in search of food; hence they were called by the ancients lucifugæ, insects that shun the light. The following species are enumerated by Linnæus and others, *viz.* gigantea, maderæ, ægyptica, occidentalis, surinamensis, americana; see Plate XV. Nat. Hist. fig. 46. australasiæ, erythocephala, capensis, indica, nivea, irrorata, viridis, brasiliensis, peliveriana, orientalis, cincta, picta, variegata, lapponica, germanica, ruficollis, maculata, marginata, oblongata, nitidula, fusca, deusta, chlorotica, latissima, aterrima, perspecillaris, asiatica, schœferi, sylvestris, pennsylvanica, livida, rufa, grisea, minutissima, aptera, punctulata, ocellata.

BLAZONING, or Blazonry, in heraldry, the art of decyphering the arms of noble families. The word originally signified the blowing or winding of a horn, and was introduced into heraldry as a term denoting the description of things borne in arms, with their proper significations and intendments, from an ancient custom the heralds, who were judges, had of winding a horn at justs and tournaments, when they explained and recorded the achievments of knights. In blazoning a coat of arms, you must always begin with the field, and next proceed to the charge; and if there are many things borne in the field, you must first name that which is immediately lying upon the field. Your expressions must be very short and expressive, without any expletives, needless repetitions, or particles. Such terms for the colours must be used, as are agreeable to the station and quality of the bearer. All persons beneath the degree of a noble, must have their colours blazoned by colours and metals; noblemen by precious stones, and kings and princes by planets.

BLEA, in the anatomy of plants, the inner rind or bark. See Physiology of Plants.

BLEACHING. The art of bleaching is of great antiquity. The ancients were acquainted with the detersive quality of some kinds of clay, and the effect produced by the action of the atmosphere, moisture, and light, on the stuffs exposed to them. Health and cleanliness rendered it necessary to devise quicker methods than these; and the property of soaps and lyes of ashes was therefore soon discovered.

In the present age, the arts, following science with close steps, have taken advantage of processes and detersive menstrua, the existence of which was before unknown; these discoveries have succeeded each other with such rapidity, that the last eight or ten years have effected a complete revolution in the art of bleaching.

This art is naturally divided into two distinct branches; the bleaching of vegetable, and of animal substances. These being of very different natures, require different processes for whitening them. Vegetables consist of oxygen, hydrogen, and carbon, of which the latter is in the greatest proportion; while animal substances, besides these, contain also a large quantity of azote, and also phosphorus and sulphur.

Bleaching of flax and hemp. If ripe flax is examined, it will be found to be composed of fibres or filaments united together by the sap, enveloping a semiligneous substance, and covered with a thin bark. It is the fibrous part only that is used for making cloth, and it must therefore be previously separated from the other matters.

The sap or succulent part is composed of extractive principle and water, and the first process is to separate this substance, which holds the filaments together. As soon as the flax is pulled, it is steeped in soft water until the putrefactive fermentation takes place. This degree of fermentation begins with the succulent part, as being more susceptible of decomposition than the rest. Was the flax to be continued long in this state, the whole substance of it would be decomposed or destroyed, upon the same principle that malt is injured by too long steeping, or that wort loses its substance by too long a fermentation. It must therefore be taken out of the water while yet green, and before the whole of its sap is separated. Well water and brackish water must be carefully avoided, as well as that which flows over gypseous soil. Such water accelerates putrefaction, and hurts the quality of the hemp and flax. This is perfectly agreeable to the principles of chymistry; it is thus that a little salt accelerates animal putrefaction, while a great quantity tends to prevent it. The portion of saline substances taken up by the water, hastens corruption, by extending the putrid fermentation even to the filaments which it blackens and spoils, while it ought to operate only on the juices.

The flax, when taken from the water, is spread out upon the grass to dry. During the fermentation and decomposition which thence result, there is a speedy combination of oxygen and carbon. Exposure on the grass facilitates the escape of the carbonic acid into the atmosphere, and the plants become of a whitish gray colour.

It is known that a lye very slightly alkaline may be substituted with advantage, for this long and noxious operation; it is therefore certain, that a chamber from 20 to 30 feet in length, into which the steam of alkaline caustic water, of the strength of one fourth of a degree only, is introduced, will be sufficient to produce the same effect as watering on an immense quantity of hemp and flax, suspended on basket work, in less time, and with less expense, than are required for the different manipulations of watering. The losses occasioned by the negligence of workmen, who, by suffering the hemp and flax to macerate too long, give time to the decomposition to reach the filaments, which renders them brittle, and occasions a considerable waste, will also be avoided. In our process, the artist can follow every moment the progress of his operation, and stop it at the favourable period.

Nothing now remains but the wood, and the flax or fibrous part. The wood is a hollow tube covered over very compactly with the flax. To separate the wood, it must be kiln dried, in order to render it frangible or brittle; but care must be taken not to apply too much heat, for fear of injuring the flax.

It is next to be beaten or broken, by which means the flax is not only divided into small fibres, but most of the wood is separated, and the part which adheres is reduced to small fragments. To separate these again, the flax is to be scutched, or threshed, in small parcels at a time, either by manual labour, or mills contrived for the pur-

pose. Hackling is the last process; which is nothing more than drawing or combining the flax in small parcels at a time, through a pile or group of polished and sharp iron spikes, placed firmly in wood through an iron plate. The spikes are placed pretty close together: the first hackle, for different hackles must be used, is coarse, the second finer, and the third finer still.

The process of hackling answers a double or triple purpose; first, it divides the fibres of the flax, as much as this can be effected by mechanical means; secondly, it separates the minute fragments of wood which escaped the process of scutching; and lastly, it separates the short coarse flax, commonly called tow.

Spinning and weaving are too well known to need description. The linen, as it comes from the loom, is charged with what they call the weaver's dressing, which is a paste of flour boiled in water; and as this is brushed into the yarn of the warp before it is woven, it is somewhat difficult to separate it when dry. To discharge this paste, the linen must be steeped in water for about forty-eight hours; when this extraneous substance undergoes a kind of fermentation, which does not extend to the substance of the linen itself, upon the same principle that the green sap is disengaged from the flax without injury to its texture.

When the linen is well washed after this last process, it contains nothing that water can separate; it is of a grayish white colour, although the fibres of which it is composed, when divested of every adventitious substance, are naturally very white.

The matter which thus colours the linen, is of a resinous nature, insoluble in water, and from its intimate union or dissemination through the very fibres of the flax, is difficult of separation, even by those substances which have a solvent power over it.

To disengage it, however, in as cheap and expeditious a manner as possible, without injuring the texture of the fabric, is the sole object of the process of bleaching.

Potash is the first menstruum which should be used in bleaching. It is most economical to render it caustic, for the purpose of bleaching. This is done by adding quicklime to the mild potash, the former having a stronger affinity for the carbonic acid than the latter. But care must be taken not to use the alkali too strong, otherwise it will attack and destroy the fibrous part. The potash, from its solvent power over the colouring matter, dissolves and separates the part immediately exposed to its action; that is, the part of it which rests superficially upon the fibres of the flax or thread; for it requires ten or twelve repeated boilings, at least, with the alternate agency of the atmosphere, to separate the whole of the resin.

It might be asked, why such an active solvent as potash should not carry away the whole of the resin at once, or at least as much as it alone could in any way separate. This requires an explanation. What appears to us to be a single ultimate fibre of flax in gray linen, is composed of a bundle of minute filaments, closely cemented or agglutinated together by the resinous matter; the potash first used therefore acts only upon the resin of the external coating of filaments; by which means they are loosened or separated, and exposed to the further action of the air. The second boiling in potash opens a second layer, and thus, successively, layer after layer, until the whole is divided, or opened to the centre. Were the solution of potash sufficiently strong to force its way at once to the centre, it would act upon the filaments themselves, and destroy the texture of the cloth.

Each filament, after the process of potash, retains an impregnation of colouring matter, so intimately united, as to resist the further action of it. This can only be removed by the slow and gradual influence of the oxygen gas of the atmosphere.

From the properties of oxygen gas and potash, their manner of operating is very obvious. The oxygen gas dissolves in each boiling a certain quantity of the colouring matter, with which it forms carbonic acid gas, and partly divides the filaments that eluded the action of potash. The carbonic acid gas, from its volatility, flies off and mixes with the atmosphere. Thus, alternately, the one dissolving, and the other burning out, for bleaching is slow combustion, the linen is whitened.

Mankind have at all times employed free air as the most convenient menstruum for bleaching. When tired with the slowness of its action, they assisted it by detersive lyes, which abridged the process a little: and this union of boiling and exposure on the grass, formed the whole of the ancient art of bleaching. Formerly, when it was necessary to bleach cloth, it was customary to immerse it in pure water, to free it from the dressing. This preliminary operation was sometimes hastened by a cold lye; the cloth was then rinsed in running water, and spread out on a meadow, round which ran a stream of limpid water that served for watering the different pieces.

After being exposed in this manner some time, the cloth was washed and boiled in a fresh lye; it was then again spread out on the grass; and this operation was several times repeated until the required whiteness was obtained. It was still necessary to wind it through soapy water, not only to give it softness and pliability, but to bleach completely the borders, which oppose the longest resistance.

It was brought to its ultimate state of whiteness by drawing it through whey, or diluted sulphuric acid. By this short description it may be seen, that a considerable time was necessary before the absorption of oxygen could take place; to hasten this operation of nature appeared impossible, until modern chymistry had demonstrated that oxygen might be extracted, and combined with water, to be afterward applied to substances where its influence might be necessary.

To promote the speedy action of atmospheric air, or rather the oxygenous part of it, in its ordinary elastic state, is well known to be impossible.

The oxygenated muriatic acid gas has been already described under the word Air. This gas, combined with water, forms the oxygenated muriatic acid, which is therefore only a combination of muriatic acid and oxygen; but this principle adheres but weakly to the muriatic acid.

All vegetable colours are attacked by this acid, and whitened with more or less celerity, which depends on their greater or less facility of combining with oxygen. The colouring matter undergoes a real slow combustion, which terminates by the formation of carbonic acid, which escaping under the form of elastic fluid, produces what we call bleaching.

In whatever manner the oxygenated muriatic acid is procured, it is evident that the oxygen adheres to it only weakly; and it is on this property that the possibility depends of producing speedily, in manufactories, that action which the atmosphere produces but slowly, and of bleaching in a space of time proportionably short.

The oxygenated muriatic acid is employed in four different ways for the purposes of bleaching; first, in the state of gas alone; secondly, in the state of gas combined with water, or what is called the acid; thirdly, potash is mixed with the acid to condense the gaseous vapour and destroy its suffocating odour; fourthly, oxygenated muriates, dissolved in water, are employed.

The first method, *viz.* employing the gas, was never used but for the purpose of experiment; as the vapour is of so noxious a quality, that to breathe it is fatal, and several people fell a sacrifice to their attempts in employing it.

When condensed in water, or in the state of oxygenated muriatic acid, it was found inconvenient in the large way, on account of the expense and difficulty in constructing the necessary apparatus, and the suffocating vapour which escaped.

For the discovery of the oxygenated muriatic acid, its effects on colouring matter, and its inestimable advantages, the arts are indebted to the justly celebrated Scheele. M. Berthollet lost no time in applying this curious and highly interesting substance to the most important practical uses. His experiments of bleaching by oxygenated muriatic acid, proved completely successful, and he did not delay to communicate his valuable labours to the public. The new method of bleaching was quickly and successfully introduced into the manufactories of Manchester, Glasgow, Rouen, Valenciennes, and Courtray; and it has since been gradually adopted in almost all parts of Great Britain, Ireland, France, and Germany. The advantages that result from this method, which accelerates the process of whitening cottons, linens, paper, &c. to a surprising degree, in every season of the year, can be justly appreciated by commercial people only, who experience its beneficial effects in many ways, but particularly in the quick circulation of their capitals.

To save the expense of first preparing the muriatic acid, the usual practice is to mix with the oxyde of manganese, muriate of soda or common salt, and sulphuric acid diluted with water. The sulphuric acid acts upon the salt, and disengages from it the muriatic acid, which is oxygenated by the oxyde of manganese. The proportions observed when cotton is to be bleached, are,

Manganese -	30 parts,
Common salt,	80
Sulphuric acid,	60
Water, -	120.

For linen cloth the proportions are as follow:

Manganese -	60 parts,
Salt, -	60
Sulphuric acid,	50
Water, -	50.

The better these substances are combined together, the more easily will the acid gas be disengaged by the action of the sulphuric acid.

To ascertain the strength of the acid for bleaching, a solution of indigo in the sulphuric acid is employed. The colour of this is destroyed by the oxygenated muriatic acid; and according to the quantity of it that can be discoloured by a given quantity of the liquor, its strength is known.

Cloth is prepared for immersion in oxygenated water, by soaking in a lye of weak potash, and rinsing it afterward in a large quantity of water, in order to free it completely from the weaver's dressing, and the saliva of the spinners.

In this country, machinery is employed for rinsing and beating; the apparatus must be arranged according to the objects to be bleached; the skains of thread must be suspended in the tub destined for them, and the cloth must be rolled upon reels in the apparatus. When every thing is thus disposed, the tubs are filled with oxygenated muriatic acid, by introducing a funnel, which descends to the bottom of the tub, in order to prevent the dispersion of the gas. The cloth is wound, or the frame work on which the skains are suspended is turned several times, until it is judged, by taking out a small quantity of the liquor from time to time, and trying it by the test of the solution of indigo, that it is sufficiently exhausted. The weakened liquor is then drawn off, and may be again employed for a new saturation.

Great difficulties for a time impeded the progress of this method of bleaching, arising chiefly from prejudice, and the ignorance of bleachers in chymical processes. These obstacles were, however, soon removed by Mr. Watt, of Glasgow, and Mr. Henry and Mr. Cooper at Manchester. Another difficulty presented itself, which had nearly proved fatal to the success of the operation. This was the want of a proper apparatus, not for making the acid and combining it with water, for this had been supplied in a very ingenious manner by Mr. Watt and M. Berthollet; but for the purpose of immersing and bleaching goods in the liquor. The volatility of this acid, and its suffocating vapours, prevented its application in the way commonly used in dye houses. Large cisterns were therefore constructed, in which pieces of stuff were stratified; and the liquor being poured on them, the cisterns were closed with lids. But this method was soon found to be defective, as the liquor could not be equally diffused; the pieces were therefore only partially bleached, being white in some parts, and more or less coloured in others.

Mr. Rupp, of Manchester, invented an apparatus for bleaching cloth, exceedingly simple in its construction, of small expense, and which contains the liquor in such a manner as to prevent the escape of the oxygenated muriatic acid gas. A consideration of no less importance in the arrangement of this apparatus, is the impossibility of the vapour injuring the health of the workmen.

It was found, however, that the use of the oxygenated muriatic acid alone weakened the cloth, and various methods of preventing its noxious effects upon the health of the workmen were tried without success; till it was discovered that an addition of alkali to the liquor deprived it of its suffocating effects, without destroying its bleaching powers. The process began then to be carried on in open vessels, and has been continued in this manner to the present period. The bleacher is now able to work his pieces in the liquor, and to expose every part of them to its action, without inconvenience.

Potash was at first used for this purpose; and although this advantage was unquestionably great, it was diminished by the heavy expense of the potash, which was entirely lost. Also, the potash which was added to the liquor, though it did not destroy its power of bleaching, diminished it; because a solution of the oxygenated muriate of potash, which differs from this bleaching liquor in nothing but in the proportion of alkali, will not bleach

at all. This is a well known fact, from which we might infer, that the oxygenated muriatic acid will lose its power of destroying the colouring matter of vegetable substances, in proportion as it becomes neutralized by potash.

It was afterward discovered that the oxymuriatic acid might be combined with the alkaline earths, as lime and barytes, and also with magnesia; by this means forming oxymuriates, which were soluble in water and had the property of bleaching. The oxymuriate of lime is at present used in almost all the bleaching grounds. For the manner of preparing it, Mr. Tennant took out a patent: but this has been lately contested, and is now prepared and used by all the bleachers through the country.

If the oxygenated muriatic acid is passed through lime water, it will combine with the lime, and form oxymuriate of lime; but as the water can only retain a small portion of lime, this was not found of much use. To cause a larger quantity of lime to combine with the oxymuriatic acid gas, the lime is mechanically suspended in the water, into which the gas is made to pass, and agitated, so as to present fresh matter to the gas. By this means, the oxymurate of lime is formed in a very convenient manner; it is dissolved in water, and used as a bleaching liquor.

This liquor is found to be preferable to the oxygenated muriatic acid, and potash. At the great bleach field in Ireland, four lyes of potash are applied alternately with four weeks exposure on the grass, two immersions in the oxygenated muriate of lime, a lye of potash between the two, and the exposure of a week on the grass between each lye and the immersions. During summer two lyes and fifteen days exposure are sufficient to prepare cloth for the action of the oxygenated muriate; then three alternate lyes, with immersions in the liquor, will be sufficient to complete the bleaching: nothing then will be necessary, but to wind the cloth through the sulphuric acid.

The oxygenated muriatic acid gas may also be combined with lime in a dry state, or the water may be evaporated, when it is employed for the formation of oxymuriates, which may then be very conveniently transported to any distance without injury to its detersive power; an advantage not possessed by the acid alone, which cannot be transported without the loss of almost half of its strength.

In all the processes for bleaching which have been hitherto described, we have seen that potash acts a distinguished part, either as an auxiliary, or as a principal agent. To find a detersive substance which might be a substitute for it, was an object of the utmost importance. Mr. Kirwan suspected that it would be found in the sulphuret of lime, and his opinion was confirmed by Dr. Higgins.

Sulphur and lime are both cheap articles; they are very easily combined, and this combination completely answers the purposes of potash, without any danger of injuring the linen. The sulphuret of lime is prepared in the following manner for the purpose of bleaching: Sulphur or brimstone, in fine powder, four pounds; lime, well slacked and sifted, twenty pounds; water, sixteen gallons; these are to be well mixed, and boiled for about half an hour in an iron vessel, stirring them briskly from time to time. Soon after the agitation of boiling is over, the solution of the sulphuret of lime clears, and may be drawn off free from the insoluble matter, which is considerable, and which rests upon the bottom of the boiler. The liquor, in this state, is pretty nearly of the colour of small beer, but not quite so transparent.

Sixteen gallons of fresh water are afterward to be poured upon the insoluble dregs in the boiler, in order to separate the whole of the sulphuret from them. When this clears, being previously well agitated, it is also to be drawn off, and mixed with the first liquor; to these again thirty-three gallons more of water may be added, which will reduce the liquor to a proper standard for steeping the cloth. Here we have, an allowance being made for evaporation, and for the quantity retained in the dregs, sixty gallons of liquor from four pounds of brimstone.

Although sulphur, by itself, is not in any sensible degree soluble in water, and lime but sparingly so, water dissolving only about one seven hundredth part of its weight of lime; yet the sulphuret of lime is highly soluble.

When linen is freed from the weaver's dressing, in the manner already described, it is to be steeped in the solution of sulphuret of lime, prepared as above, for about twelve or eighteen hours, then taken out and very well washed. When dry, it is to be steeped in the oxymuriate of lime for twelve or fourteen hours, and then washed and dried. This process is to be repeated six times, that is, six alternate immersions in each liquor, which has been found to whiten the linen.

Steam has been lately employed with great success in France. The process was brought from the Levant. Chaptal first made it known to the public.

We have already mentioned, that the bleaching of vegetable substances depends on the destruction of their colouring principle by the combined action of the air, moisture, and light; or rather, by the united influence of these principles to alter their natural colour.

Alkalies have, on the colouring matter of vegetables, an action which produces the effect of a real combustion. Were we intimately acquainted with the nature of potash and soda, we might be able to explain the cause of this burning; but it is sufficient for us at present to know the effect. The exposure of vegetable matters on the grass, subjects them to the action of the solar rays; and moistening them during their exposure, facilitates, with the evaporation of the water, the emanation of the carbonic acid formed by the oxygen of the atmosphere, which combines with the carbon resulting from the alkaline combustion. It even agrees pretty well with theory, in terminating the process of bleaching, to immerse the cloth and thread in sour milk, acidulous liquors, or, what is more convenient, very weak sulphuric acid.

In proportion as the alkali, during the first immersion, destroys the colouring matter, the oxygen of the atmosphere, or that furnished by the oxygenated muriatic acid, joins that carbonized matter, and forms carbonic acid, which afterward resolves itself into gas. This is contained the more in the principles, as the bases of all the acids are insoluble in water; but when the combination takes place between the carbon and the oxygen, it immediately becomes soluble. Thus, on the one hand to burn the colouring matter, and to dissolve it on the other, form the whole secret of the art of bleaching; and the greater or less tendency of vegetable substances to experience that combustion, constitutes the gradations of their whiteness, and the facility or difficulty of bleaching.

The slowness of the whole process arose, in a great measure, from bleachers being unacquainted with these principles. A long succession of lyes, and exposure on the grass, was necessary to penetrate the fibres of the linen from stratum to stratum. The texture was sufficiently close to resist the action of the heat of a common lye, and a considerable time was required to absorb the oxygen presented by the delicate stratum of atmospheric air.

In the process of bleaching by steam, these difficulties are removed. The high temperature of the steam, in the interior part of the apparatus, swells up the fibres of the thread or cloth; the pure alkali, which rises with the elastic fluid, seizes with avidity on the colouring matter, and burns it; seldom does the tissue of the flax or hemp resist the penetrating effect of this vapour bath. The whole matter, therefore, by which they are coloured, is attacked and decomposed by this single operation; and even if we suppose that a part has been able to resist, nothing is necessary but to repeat the operation, after a previous immersion and exposure on the grass, to ensure its complete effect. The alkali even appears to have a much livelier and more caustic action when it is combined with caloric, than in ordinary lyes, where the temperature never rises above 162° of Fahrenheit. By making the cloth or thread pass through one lye of oxygenated muriatic acid, or oxygenated muriate of lime, an union is effected between the solution and the carbon, arising from the burning of the extracto mucous matter of the flax; carbonic acid is formed; the water even in which this new compound is diluted, concurs to promote this combination: if the cloth is then exposed on the grass, the carbonic acid is dissipated, and the cloth is bleached.

It was believed that the steam of a pure alkakine lye would not be caustic, and would not produce the same effects as the saline solution; and the reason assigned for this opinion was the concentration of all the salts by the evaporation of the aqueous fluid: but what takes place in the open air, where the atmosphere every moment absorbs the moisture which is evaporated, cannot be applied to a close apparatus, where the temperature is elevated in an extreme degree: besides, the caloric always carries with it a little alkali, even in low temperatures, as is observed when water is poured over potash; the steam which issues from it changes blue vegetable colours to green.

It follows from these chymical principles, that the action of steam alone does not bleach, and that the concurrence of oxygen is necessary to aid the composition of the carbonic acid; this acid requires for its formation, 28 parts of carbon, saturated with 72 of oxygen: but all the oxygen contained in the apparatus would not be sufficient to saturate the considerable quantity of colouring matter burnt by the alkaline combustion, and converted into carbon; this deficit must be supplied by immersion in any oxygenated liquor whatever, and the dispersion of the elastic fluid thus formed must be then facilitated by exposure on the grass.

To bleach cloth in this manner, it must be immersed in a slight alkaline caustic liquor, and placed in a chamber constructed over a boiler, into which is put the alkaline lye which is to be raised into steam. After the fire has been lighted, and the cloth has remained exposed to the action of the steam for a sufficient length of time, it is taken out, and immersed in the oxygenated muriate of lime, and afterward exposed for two or three days on the grass. This operation, which is very expeditious, will be sufficient for cotton; but if linen cloth should still retain a yellow tint, a second alkaline caustic vapour bath, and two or three days on the grass, will be sufficient to give it the necessary degree of whiteness.

Bleaching of cotton. Cotton is a filamentous substance, or a kind of down which envelops the seeds of the cotton plant. This plant or shrub comes originally from the East, and grows only in warm climates.

This substance, after being separated from the seeds, is always charged with a coarse colouring matter, which soils it, and renders it opaque. The presence of this unctuous matter is proved by the slowness with which cotton absorbs water before it is scoured, and by the force with which it absorbs it after the operation; by which means, from being opaque, it is rendered clear and transparent.

Cotton varies a great deal in its qualities, according to the different kinds, the climate where produced, and the culture employed. Its colour is sometimes yellow, and sometimes white; but in general it is of a dirty yellow.

To bleach it does not require the same preparations as hemp and flax. The first operation consists in scouring it in a slight alkaline solution, or, what is better, by exposure to steam. It is afterward put into a basket, and rinsed in running water. The immersing of cotton in an alkaline lye, however it may be rinsed, always leaves with it an earthy deposite. It is well known that cotton bears the action of acids better than hemp or flax; that time is even necessary before the action of them can be prejudicial to it: and by taking advantage of this valuable property in regard to bleaching, means have been found to free it from the earthy deposite, by pressing down the cotton in a very weak solution of sulphuric acid, and afterward removing the acid by washing, lest too long remaining in it should destroy the cotton.

Bleaching of wool. The substances produced by the animal kingdom, differ essentially in their constituent principles from vegetables. Vegetables serve as the nourishment to the animals and insects, the spoils of which we employ. Animalized by their organs, they acquire other properties. We shall here confine ourselves to the examination of wool and silk, as the animal substances most generally employed for clothing.

Wool is a finer kind of hair with which the bodies of several animals are covered. It is composed of filaments or tubes, filled with an oily or medullary substance. The sides of these tubes are perforated with a multitude of small pores which communicate with a longitudinal tube. By chymical analysis wool gives a great deal of oil, and carbonate of ammonia; caustic alkaline lyes dissolve it entirely. It experiences no change in boiling water; it alters very little when preserved in a place well aired; acids have very little action on it; when exposed to a strong heat, it enters into fusion.

An examination of these chymical facts, is necessary for understanding the principles which ought to direct the artist in the bleaching of this substance. The little action which acids have upon wool, and its unalterableness in water even when aided by heat, render it necessary to have recourse to alkaline or saponaceous lyes; but its solubility in these salts shows, that great prudence and caution must be employed. In regard to acids, none have been

hitherto used but the sulphureous acid, obtained in the gaseous state by combustion.

In the preliminary operations to which wool is subjected, it is customary to leave a little of its grease, to secure it from insects. Wool is often freed from the grease by the farmers, when they wish to sell it at a high price; but in the subsequent manipulations, it is greased or oiled before it is combed, spun, &c. and as this fat matter attracts dust, it dirties and thickens the stuffs. The first kind of bleaching to which wool is subjected, is to free it from these impurities. This operation is called scouring. In manufactories, it is generally performed by means of an ammoniacal lye, formed of five measures of river water and one of stale urine; the wool is immersed for about twenty minutes in a bath of this mixture, heated to fifty-six degrees; it is then taken out, suffered to drain, and then rinsed in running water: this manipulation softens the wool, and gives it the first degree of whiteness; it is repeated a second, and even a third time, after which the wool is fit to be employed. In some places, scouring is performed with water slightly impregnated with soap; and indeed, for valuable articles, this process is preferable, but it is too expensive for articles of less value.

Fulling the cloth adds still to the whiteness, and if an increased degree is necessary, it may be procured by the action of the sulphureous acid; that is to say, of the fumes of sulphur in a state of combustion, or the vapour of that acid condensed and combined with water.

Snlphuring is generally performed in an arched or very close chamber, constructed in such a manner, that the articles to be exposed to the action of the sulphur can be suspended on poles. The chamber being filled, a certain quantity of sulphur is put in a state of combustion in flat dishes, having a large surface with very little depth; the entrance is speedily shut, and all the interstices around the door are carefully stopped to prevent the access of the atmospheric air. The acid generated by the combustion of the sulphur, penetrates the stuffs, attacks the colouring matter, destroys it, and effects the bleaching. The stuffs are left in the stoves some time after the deflagration has ceased. This time varies from six to twenty-four hours. They are then taken out, and made to pass through a slight washing with soap, to remove the roughness they have acquired by the action of the acid, and to give them the necessary softness.

This process is imperfect. At first, the acid of the sulphur acts only on the surfaces, and does not penetrate. This aerial immersion is not sufficient; the gas cannot introduce itself to a sufficient depth into the stuffs, and the superficies only are whitened.

A superior method has been lately invented, which is by making use of the sulphureous acid.

The sulphureous acid, or that acid generated by the imperfect combustion of sulphur, differs from the sulphuric acid, oil of vitriol, by its containing less of the acidifying principle, and by being the mean term between the sulphuric acid.

Sulphureous acid gas unites very easily with water, and in this combination it may be employed for bleaching wool and silk. The sulphureous acid in this state of liquidity, may be prepared by making it traverse water in an apparatus nearly similar to that used for preparing oxygenated muriatic acid. The most economical method of obtaining it is to decompose sulphuric acid, oil of vitriol, by the mixture of any combustible matter capable of taking from it a part of its oxygen. In exact experiments of the laboratory, when the chymist is desirous of having great purity, it is obtained by means of metallic substances, and particularly by mercury; but for the purpose of which we are treating, where great economy is required, we should recommend the most common substances. We shall therefore give the following process. Take chopped straw, or sawdust, and introduce it into a mattress; pour over it sulphuric acid, applying at the same time heat, and there will be disengaged sulphureous acid gas, vapour of sulphur, which may be combined with water in the apparatus.

The pieces are rolled upon the reels, and are drawn through the sulphureous acid by turning them, until it is observed that the whiteness is sufficiently bright. They are then taken out, and are left to drain on a bench covered with cloth, lest they should be stained in consequence of the decomposition of the wood by the sulphureous acid; they are next washed in river water, and Spanish white is employed, if it should be judged necessary. This operation is performed by passing the pieces through a tub of clear water, in which about eight pounds of Spanish white have been dissolved. To obtain a fine whiteness, the stuffs, in general, are twice sulphured. According to this process, one immersion and reeling two or three hours are sufficient. Azuring or bluing is performed by throwing into the Spanish white liquor, a solution of one part of Prussian blue to 400 parts of water; shaking the cloth in the liquid, and reeling it rapidly. The operation is terminated by a slight washing with soap, to give softness and pliability to the stuffs. The final operations of drying, stretching, pressing, &c. are foreign to our present subject.

Bleaching of silk. Silk is a semitransparent matter, spun by a caterpillar, and formed of a substance contained in its body, which becomes hard in the air. This insect inhabits warm climates, being indigenous in Asia: it was naturalized in Europe about the time of the downfal of the Roman empire.

The filaments prepared by the silkworm are rolled up in a cod or ball. In this state, in which we find it, it is covered with a yellow varnish, which destroys its brilliancy and renders it rough. Silk by chymical analysis gives carbonate of ammonia and oil; water at a boiling heat produces no effect upon it; alcohol makes it experience no change; but concentrated alkaline lyes attack and dissolve it.

To give splendour to silk, it must be freed from its varnish. This covering is soluble in alkaline lyes. Silk is generally scoured by means of soap, by which it loses one fourth of its weight. The matter disengaged from it is very fetid, and if the silk is not rinsed in plenty of water, putrid fermentation will take place. Even when the best soap is used, it is generally suspected that it injures the whiteness of the silk. The splendour of the Chinese silk is brighter than that of the European, and the Chinese employ no soap in their operations. A slightly alkaline lye will dissolve the varnish of the silk without using soap, and this has also been effected by the action of boiling water at a very high temperature.

The method which has been used successfully in France is as follows:

Take a solution of caustic soda, so weak as to mark only a fourth of a degree, at most, of the arcometer for salts,

and fill with it the boiler of the apparatus for bleaching with steam. Charge the frames with skains of raw silk, and place them in the apparatus until it is full; then close the door, and make the solution boil. Having continued the ebullition for twelve hours, slacken the fire, and open the door of the apparatus. The heat of the steam, which is always above 250°, will have been sufficient to free the silk from the gum, and to scour it. Wash the skains in warm water; and, having wrung them, place them again on the frames in the apparatus, to undergo a second boiling. Then wash them several times in water, and immerse them in water somewhat soapy, to give them a little softness.

Notwithstanding the whiteness which silk acquires by these different operations, it must be carried to a higher degree of splendour by exposing it to the action of sulphureous acid gas, in a close chamber, or by immersing it in sulphureous acid, as before recommended for wool.

Bleaching prints, and printed books. An application has been made of the new mode of bleaching, to the whitening of books and prints that have been soiled by smoke and time.

Simple immersion in oxygenated muriatic acid, letting the article remain in it a longer or shorter space of time according to the strength of the liquid, will be sufficient to whiten an engraving: if it is required to whiten the paper of a bound book, as it is necessary that all the leaves should be moistened by the acid, care must be taken to open the book well, and to make the boards rest on the edge of the vessel, in such a manner that the paper alone shall be dipped in the liquid: the leaves must be separated from each other, in order that they may be equally moistened on both sides.

The liquor assumes a yellow tint, and the paper becomes white in the same proportion; at the end of two or three hours, the book may be taken from the acid liquor, and plunged into pure water, with the same care and precaution as recommended in regard to the acid liquor, that the water may exactly touch the two surfaces of each leaf. The water must be renewed every hour, to extract the acid remaining in the paper, and to dissipate the disagreeable smell.

By following this process, there is some danger that the pages will not be all equally whitened; either because the leaves have not been sufficiently separated, or because the liquid has had more action on the front margins than on those near the binding. On this account, the best way is to destroy the binding entirely, that each leaf may receive an equal and perfect immersion; and this is the second process recommended by M. Chaptal.

"They begin," says he, "by unsewing the book, and separating it into leaves, which they place in cases formed in a leaden tub, with very thin slips of wood or glass, so that the leaves, when laid flat, are separated from each other by intervals scarcely sensible. The acid is then poured in, making it fall on the sides of the tub, in order that the leaves may not be deranged by its motion. When the workman judges, by the whiteness of the paper, that it has been sufficiently acted upon by the acid, it is drawn off by a cock at the bottom of the tub, and its place is supplied by clear fresh water, which weakens and carries off the remains of the acid, as well as the strong smell. The leaves are then to be dried, and after being pressed, may be again bound up.

"The leaves may be placed also vertically in the tub; and this position seems to possess some advantage, as they will be less liable to be torn. With this view I constructed a wooden frame, which I adjusted to the proper height, according to the size of the leaves which I wished to whiten. This frame supported very thin slips of wood, leaving only the space of half a line between them. I placed two leaves in each of these intervals, and kept them fixed in their place by two small wooden wedges, which I pushed in between the clips. When the paper was whitened I lifted up the frame with leaves, and plunged them in cold water, to remove the remains of the acid, as well as the smell; this process I prefer to the other.

"By this operation books are not only cleaned, but the paper acquires a degree of whiteness superior to what it possessed when first made. The use of this acid is attended also with the valuable advantage of destroying ink spots. This liquor has no action upon spots of oil or animal grease; but it has been long known that a weak solution of potash will effectually remove stains of that kind.

"When I had to repair prints so torn that they exhibited only scraps pasted upon other paper, I was afraid of losing these fragments in the liquid, because the paste became dissolved. In such cases I enclosed the prints in a cylindric glass vessel, which I inverted on the water in which I had put the mixture proper for extricating the oxygenated muriatic acid gas. This vapour, by filling the whole inside of the jar, acted upon the print, extracted the grease as well as ink spots, and the fragments remained pasted to the paper."

Easy method of preparing the oxygenated muriatic acid. To oxygenate the muriatic acid, nothing is necessary but to dilute it, and mix it in a very strong glass vessel with manganese, in such a manner that the mixture may not occupy the whole contents of the glass. Air bubbles are formed on the surface of the liquor; the empty space becomes filled with a greenish vapour; and at the end of some hours the acid may be further diluted with water, and then used. It has an acid taste, because the whole is not saturated with oxygen; but it possesses all the virtues of the oxygenated muriatic acid. This process may be followed when there is not time to set up an apparatus for distilling, in order to procure the oxygenated acid.

BLECHNUM, in botany, a genus of plants of the class of the cryptogamia filices; the fructifications of which are disposed in two parallel lines, approaching to the rib of the frond. There are six species, all foreign plants.

BLEEDING. See Surgery.

BLENDE, or Black Jack. This ore very usually accompanies sulphuret of lead. It is common, but seldom in such quantities as to make it worth working. It occurs both in amorphous masses and crystalized. The primitive form of its crystals is the rhomboidal dodecahedron. The figure of its integrant particles is the tetrahedron.

Colour yellow, brown, or black. Streak reddish, brownish, or gray. Lustre vitreous, or that of the diamond. Generally somewhat transparent. Refraction single. Texture foliated. Clivage six fold. Hardness 6 to 8. Scratches sulphat of barytes. Specific gravity 4.000 to 4.1665. Before the blow pipe decrepitates, and gives out white

flowers of zinc, but does not melt. Borax does not affect it. When breathed upon, loses its lustre, and recovers it very slowly. It is usually divided into three subspecies.

1. Yellow blende. Colour commonly sulphur yellow, often passing into olive green or brownish red. Powder pale yellow. Streak yellowish or reddish gray, not metallic. Lustre that of the diamond. Transparency usually 2, sometimes 4. Often phosphoresces when scraped or rubbed. According to Bergmann, it is composed of

64 zinc
20 sulphur
5 iron
4 fluoric acid
1 silica
6 water

100.

2. Brown blende. Colour different shades of brown. Surface often tarnished. Powder brownish gray. Streak yellowish gray. Lustre internal, vitreous. Transparency 0 to 2, sometimes 4. A specimen of this variety, analyzed by Bergmann, contained

44 zinc
17 sulphur
24 silica
5 iron
5 alumina
5 water

100.

3. Black blende. Colour black or brownish black; surface often tarnished blue; tips of the crystals often blood red. Powder brownish black. Streak reddish gray. Lustre internal, that of the diamond. Transparency 0 to 1; the red parts 2. Hardness 8. A specimen of this variety, analyzed by Bergmann, contained

52 zinc
26 sulphur
4 copper
8 iron
6 silica
4 water

100.

BLENNIUS, the Blenny, a genus of fishes belonging to the order of jugulares; the characters of which are: the head slants or declines to one side; there are six rays in the membrane of the gills; the body tapers toward the tail; the belly fins have only two blunt bones; and the tail fin is distinct. The species are 13, among which are:

1. Blennius cornutus, with a simple ray above the eyes, and a single back fin. 2. Blennius galeria, with a transverse membraneous crest upon the head, is found in the European seas. 3. Blennius gattorugine, see Plate XV. Nat. Hist. fig. 47. with small palmated fins about the eyebrows and neck. It is about seven or eight inches long, and is found in the European seas. 4. Blennius ocellaris, fig. 48. with a furrow betwixt the eyes, and a large spot on the back fin. It is found in the European seas. 5. Blennius raninus, with six divisions in the belly fins, is found in the lakes of Sweden. It is remarkable that when this fish appears in the lake, all the other fishes retire; and what is worse, it is not fit for eating. 6. Blennius viviparus, has two tentacula at the mouth. They bring forth 200 or 300 young at a time. Their season of parturition is a little after the depth of winter. Before midsummer they quit the bays and shores, and retire into the deep, where they are commonly taken. They are a very coarse fish, and eaten only by the poor. They are common in the mouth of the Esk, at Whitby, Yorkshire, where they are taken frequently from off the bridge. They sometimes grow to the length of a foot. Their form is slender, and the back bone is as green as that of a sea needle. See Plate, Nat. Hist. fig. 49.

BLIGHT, in husbandry, a disease incident to plants, which affects them variously, the whole plant sometimes perishing by it, and sometimes only the leaves and blossoms, which will be scorched and shrivelled up, the rest remaining green and flourishing. Various causes have been assigned for this disease, and various cures proposed. It sometimes is in the plant itself from imperfect secretion, but is more commonly the effect of cold winds in the spring. See Plants.

BLINDS, or Blindes, in the art of war, a sort of defence commonly made of osiers, or branches interwoven and laid across between two rows of stakes, about the height of a man, and four or five feet asunder, used particularly at the heads of trenches when they are extended in front toward the glacis; serving to shelter the workmen, and prevent their being overlooked by the enemy.

BLINDNESS, a total privation of sight, arising from an obstruction of the functions of the organs of sight, or from an entire deprivation of them.

The causes of blindness are various; proceeding from cataracts, gutta serena's, &c. There are also periodical blindness, as a defect of sight in some toward night, in others only in the day; the former of which is termed nyctalopia, the latter hemeralopia.

It is said, that in several parts of Persia, there are found vast numbers of blind people of all ages, sexes, and conditions, occasioned by a species of little flies, which prick the eyes and lips, and enter the nostrils, carrying certain blindness with them when they light on the eyes.

If we consider blindness in a moral or philosophical view; as there is not any sense or faculty of the corporeal frame which affords so many sources of utility and entertainment as the power of vision; so is there not any privation which can be productive of disadvantages so various and so bitter as the want of sight. By no avenue of corporeal perception is knowledge, in her full extent, so accessible to the rational soul, as by the glorious and delightful medium of light. To the blind, on the contrary, the visible universe is totally annihilated; he has not even any distinct idea of space, except that in which he stands, or to which his extremities can reach. Sound, indeed, gives him some ideas of distant objects; but these ideas are extremely obscure and indistinct. They are obscure, because they consist alone of the objects whose oscillations vibrate on his ear, and do not necessarily suppose any other bodies with which the intermediate space may be occupied; they are indistinct, because sounds themselves are frequently ambiguous, and do not uniformly in-

dicate their real causes. And though by them the idea of distance in general, or even of some particular distances, may be obtained; yet they never fill the mind with those vast and exalting ideas of extension which are inspired by ocular perception. For though a clap of thunder, or an explosion of ordnance, may be distinctly heard after the sound has traversed an immense region of space, yet, when the distance is uncommonly great, it ceases to be indicated by sound; and therefore the ideas acquired by auricular experiments, of extension and interval, are extremely confused and inadequate. The comprehensive eye darts its instantaneous glance over extensive vallies, lofty mountains, protracted rivers, illimitable oceans. It views in an instant the mighty space from earth to heaven, or from one star to another. By the assistance of telescopes, its power is almost infinitely extended, its objects multiplied, and the sphere of its observation immensely enlarged. Thus the imagination, inured to vast impressions of distance, can not only recal them in their greatest extent, with as much rapidity as they were at first imbibed, but can multiply them, and add one to another, till all particular boundaries and distances are lost in immensity. The blind are apprehensive of danger in every motion toward any place, whence their contracted powers of perception can give them no intelligence. All the various modes of delicate proportion, all the beautiful varieties of light and colours, exhibited in the works of nature and art, are to them irretrievably lost. Dependent for every thing, but mere existence, on the good offices of others; obnoxious to injury from every point, which they are neither capacitated to perceive nor qualified to resist; they are, during the present state of being, rather prisoners at large, than citizens of nature. The sedentary life to which by privation of sight they are destined, relaxes their frame, and subjects them to all the miserable sensations which arise from dejection of spirits. Hence the most feeble exertions create lassitude and uneasiness. Hence the native tone of the nervous system, compatible with health and pleasure, being destroyed by inactivity, exasperates and imbitters every disagreeable impression. Natural evils, however, are supportable, being either mild in their attacks, or short in their duration: the miseries inflicted by conscious and reflecting agents almost alone deserve the name of evils. These excruciate the soul with ineffable poignancy, as expressive of indifference or malignity in those by whom such bitter potions are cruelly administered. The negligence or wantonness, therefore, with which the blind are too frequently treated, is an enormity which God alone has justice or power to punish. Those amongst them who have had sensibility to feel, and capacity to express, the effects of their misfortunes, have described them in a manner capable of penetrating the most callous heart. Homer, in the person of Demodocus the Phæatian bard, has pathetically described his own situation; and Milton, with equal force and beauty, has deplored the misfortune of blindness.

Thus dependent on every creature, and passive to every accident, can we be surprised to observe moments when the blind are at variance with themselves and every thing else around them? With the same instinct of self preservation, the same irascible passions which are common to the species, and exasperated by a sense of debility either for retaliation or defence, can the blind be really objects of resentment or contempt, even when they seem peevish or vindictive? This, however, is not always their character. Their behaviour is often highly expressive not only of resignation, but even of cheerfulness; and though they are often coldly, and even inhumanly, treated by men, yet they are rarely, if ever, forsaken of Heaven. The common Parent of nature, whose benignity is permanent as his existence, and boundless as his empire, has neither left his afflicted creatures without consolation nor resource.

The blind often derive advantages even from their loss, however oppressive and irretrievable: not indeed adequate to compensate, but sufficient to alleviate their misery. The attention of the soul, confined to those avenues of perception which she can command, is neither dissipated nor confounded by the immense multiplicity, nor the rapid succession, of surrounding objects. Hence her contemplations are more uniformly fixed upon the revolutions of her own internal frame. Hence her perceptions of such external things as are contiguous and obvious to her observation, become more exquisite. Hence even her instruments of corporeal sensation are more assiduously improved: so that from them she derives such notices of approaching pleasure, or impending danger, as entirely escape the attention of those who depend for security on the reports of their eyes. He distinguishes the approach of his friend by the sound of his steps, by his manner of breathing, and almost by every audible token which he can exhibit. Prepared for the dangers which he may encounter from the surface of the ground upon which he walks, his step is habitually firm and cautious. Hence he not only avoids those falls which might be occasioned by its less formidable inequalities, but from its general bias he collects some ideas how far his safety is immediately concerned; and though these conjectures may be sometimes fallacious, yet they are generally so true as to preserve him from such accidents as are not incurred by his own temerity. The rapid torrent and the deep cascade not only warn him to keep a proper distance, but inform him in what direction he moves, and are a kind of audible cynosures to regulate his course. In places to which he has been accustomed, he in a manner recognises his latitude and longitude from every breath of varied fragrance that tinges the gale, from every ascent or declivity in the road, from every natural or artificial sound that strikes his ear; if these indications be stationary, and confined to particular places. Regulated by these signs, the blind have not only been known to perform long journies themselves, but even, if we may credit report, to conduct others through dangerous paths at midnight, with the utmost security and exactness.

It would be endless to recapitulate the various mechanical operations of which they are capable by their nicety and accuracy of touch. In some, the tactile powers are said to have been so highly improved, as to perceive that texture and disposition of coloured surfaces by which some rays of light are reflected and others absorbed, and in this manner to distinguish colours; but the testimonies for this fact still appear too vague and general to deserve public credit. A person who lost the use of his sight at an early period of infancy, who in the vivacity or delicacy of his sensations was not perhaps inferior to any one, and who had often heard of others in his situation capable of distinguishing colours by touch, stimulated, partly by curiosity

to acquire a new train of ideas if possible, but still more by incredulity with respect to the facts related, tried repeated experiments by touching the surfaces of different bodies and examining whether any such diversities could be found in them as might enable him to distinguish colours; but no such diversity could he ever ascertain. Sometimes, indeed, he imagined that objects which had no colour, or, in other words, such as were black, were somewhat different and peculiar in their surfaces, but this experiment did not always hold. That their acoustic perceptions are distinct and accurate, we may fairly conclude from the rapidity with which they ascertain the acuteness or gravity of different tones, and from their exact discernment of the various modifications of sound, and of sonorous objects, if the sounds themselves are in any degree significant of their causes.

When we ruminate on the numberless advantages derived from the use of sight, and its immense importance in extending the human capacity, and improving every faculty of the mind, we might be tempted to doubt the reports concerning such persons as, without the assistance of light, have arrived at high degrees of eminence even in those sciences which appear absolutely unattainable but by the interposition of external mediums. It has, however, been demonstrated by the late ingenious Dr. Reid, that blind men, by proper instruction, are susceptible of almost every idea, and every truth which can be impressed on the mind by the mediation of light and colours, except the sensations of light and colours themselves. Yet there is one phenomenon of this kind which seems to have escaped the attention of that philosopher, and for which no author has offered any tolerable reason, though it certainly merits the attention of a philosopher. For though we should admit that the blind can understand with great perspicuity all the phenomena of light and colours; though it was allowed that on these subjects they might extend their speculations beyond their instructions, and investigate the mechanical principles of optics by the mere force of genius and application, from the data which they have already obtained; yet it will be difficult, if not impossible, to assign any reason why these objects should be more interesting to a blind man than any other abstract truths whatever. It is possible for the blind, by a retentive memory, to tell that the sky is an azure; that the sun, moon, and stars, are bright; that the rose is red, the lily white or yellow, and the tulip variegated. By continually hearing these substantives and adjectives joined, he may be mechanically taught to join them in the same manner; but if he has never had any sensation of colour, however accurately he may speak of coloured objects, his language must be like that of a parrot; without meaning, and without ideas.

It is scarcely possible to lay down a plan, or enter into a detail of particulars, with respect to the mode of education proper to be pursued for the blind. These must be determined by the genius, the capacity, and the circumstances, of those to whom the general rules should be applied. Much therefore must depend on their fortunes, much on their temper and genius; for unless these particulars were known, every answer which could be given to questions of this kind must be extremely general, and of consequence extremely superficial. Besides, the task is so much more arduous, because whoever attempts it can expect to derive no assistance from those who have written on education before him: and though the blind have excelled in more than one science, yet, except in the case of Dr. Saunderson, it does not appear that any of them have been conducted to that degree of eminence at which they arrived upon a premeditated plan. We should rather imagine, that they have been led through the general course and ordinary forms of discipline; and that, if any circumstances were favourable to their genius, they rather proceeded from accident than design. This melancholy truth reflects no honour on human nature. When contemplated by a man of benevolence, it is not easy to guess whether his mortification or astonishment will be greatest. A heart that glows with real philanthropy feels for the whole vital creation, and becomes in some measure the sensorium of every suffering insect or reptile. How must our sympathy increase then in tenderness and force, when the distressed individuals of our own species become its objects! Nor do the blind bear so small a proportion to the whole community as, even in a political view, to be neglected. But in this, as in every other political crime, the punishment returns upon the society in which it is committed. Those abandoned and unimproved beings, who, under proper culture and discipline, might have successfully concurred in producing and augmenting the general welfare, become the nuisances and burdens of those very societies who have neglected them. The most important view which we can entertain in the education of a person deprived of sight, is to redress, as effectually as we possibly can, the natural disadvantages with which he is encumbered; or, in other words, to enlarge as far as possible the sphere of his knowledge and activity. This can only be done by the improvement of his intellectual, imaginative, or mechanical, powers; and which of these ought to be most assiduously cultivated, the genius of every individual alone can determine. Were men to judge of things by their intrinsic natures, less would be expected from the blind than others. But, by some pernicious and unaccountable prejudice, people generally hope to find them either possessed of preternatural talents, or more attentive to those which they have than others. Hence it unluckily happens, that blind men, who in common life are too often regarded as raree shows, when they do not gratify the extravagant expectations of their spectators, frequently sink in the general opinion, and appear much less considerable and meritorious than they really are. This general diffidence of their powers deprives them both of opportunity and spirit to exert themselves; and they descend, at last, to that degree of insignificance in which the public estimate has fixed them. From the original dawning, therefore, of reason and spirit, the parents and tutors of the blind ought to inculcate this maxim upon them; that it is their indispensable duty to excel, and that it is absolutely in their power to attain a high degree of eminence. Not that improvement should be rendered quite easy to them: for all difficulties which are not insuperable heighten the charms, and enhance the value, of those acquisitions which they seem to retard. But care should be taken that these difficulties be not magnified or exaggerated: for the blind have a painful sense of their own incapacity, and consequently a strong propensity to despair. For this reason, parents and relations ought never to be too ready in offering their assistance to the blind

in any office which they can perform, or in any acquisition which they can procure for themselves, whether they are prompted by amusement or necessity. Let a blind boy be permitted to walk through the neighbourhood without a guide, not only though he should run some hazard, but even though he should suffer some pain. If he has a mechanical turn, let him not be denied the use of edge tools: for it is better that he should lose a little blood, or even break a bone, than be perpetually confined to the same place, debilitated in his frame, and depressed in his mind. Such a being can have no employment but to feel his own weakness, and become his own tormentor; or to transfer to others the peevishness arising from the natural, adventitious, or imaginary, evils which he feels. Scars, fractures, and dislocations, in his body, are trivial misfortunes compared with imbecility, timidity, or fretfulness, of mind. Besides the dreadful effects which inactivity has in relaxing the nerves and depressing the spirits, nothing can be more productive of jealousy, envy, peevishness, and every passion that corrodes the soul to agony, than a painful impression of dependence on others, and of our insufficiency for our own happiness. The natural curiosity of children renders them extremely inquisitive. This disposition is often peculiarly prevalent in the blind. Parents and tutors, therefore, should gratify it whenever their answers can be intelligible to the pupil: when it is otherwise, let them candidly confess the impossibility or impropriety of answering his questions. Nor will the violence of exercise, and the tumult of play, be productive of such perils as may be apprehended. For the encouragement of parents, we can assure them, that though, till the age of twenty, some blind persons were, on most occasions, permitted to walk, to run, to play at large, they have yet escaped without any corporeal injury from these excursions. Parents in the middle, or higher ranks, who have blind children, ought, by all means, to keep them out of vulgar company. Such persons often have a wanton malignity, which impels them to impose upon the blind, and to enjoy their painful sensations. But the credulity and ignorance of the lower class are no less dangerous than their false wit. The illiterate have often a strong propensity to relate whatever is marvellous and dreadful. These impressions, when early imbibed, can scarcely be eradicated by all the conspiring efforts of mature reason and confirmed experience. Those philosophers who have attempted to break the alliance between darkness and spectres, were certainly inspired by laudable motives. Were we endued with senses to advertise us of every noxious object before its contiguity could render it formidable, our panics would probably be less frequent and sensible than we really feel them. Darkness and silence, therefore, have something dreadful in them, because they supersede the vigilance of those senses which give us the earliest notices of things. In talking, therefore, to a blind boy of invisible beings, let him hear as seldom as possible, even in stories which he knows to be fabulous, of vindictive ghosts, vindictive fiends, or avenging furies. They seize and preoccupy every avenue of terror which is open in the soul; nor are they easily dispossessed. Sooner may we hope to exorcise a ghost, than to obliterate their images in a warm and susceptible imagination, where they have been habitually impressed, and where these feelings cannot be dissipated by external phenomena. If horrors of this kind should agitate the heart of a blind boy, which may happen, notwithstanding the most strenuous endeavours to prevent it, the stories which he has heard will be most effectually discredited by ridicule. This, however, must be cautiously applied, by gentle gradations. If he is inspired with terror by effects upon his senses, the causes of which he cannot investigate, pains must be taken to explain these phenomena; and to confirm that explication, whenever it can be done, by the testimony of his own senses and his own experience. The exercise of his locomotive and mechanical powers will sensibly contribute to dispel these terrors. His inventive faculties ought likewise to be indulged with the same freedom. The data which they explore may be presented in such a manner as to render discoveries easy: but still let invention be allowed to co-operate. The internal triumph which the mind feels from the attainment of new truths, heightens their charms, impresses them deep on the memory, and gives them a lasting influence in practice. Care should therefore be taken to afford the mind a theatre for its exertions, as extensive as possible, without diverting it from one great end, which, in order to excel, it ought for ever to have in view.

With respect to employments for the blind, if the pupil be not in easy circumstances, music is his readiest and most probable resource. Civil and ecclesiastical employments have either something in their own nature, or in the invincible prejudices of mankind, which renders them entirely inaccessible to such as have not the use of sight. No liberal and cultivated mind can entertain the least hesitation in concluding, that there is nothing, either in the nature of things, or even in the positive institutions of genuine religion, repugnant to the idea of a blind clergyman. As to the law, though there could be no doubt that a blind man might discharge the office of a chamber counsel with success, yet, as a barrister, his difficulties must appear formidable, if not absolutely insuperable: for he must remember all the sources, whether in natural equity or positive institutions, whether in common or statute law, whence his arguments ought to be drawn. He must be able to specify, and to arrange in their proper order, all the material objections of his antagonists: these he must likewise answer as they are proposed, extempore. When, therefore, it is considered how difficult it is to temper the natural associations of memory with the artificial arrangements of judgment, the desultory flights of imagination with the calm and regular deductions of reason, the energy and perturbation of passion with the coolness and tranquillity of deliberation, some idea may be formed of the arduous task which every blind man must achieve, who undertakes the law as a profession. As to physic, the obstacles which a blind man must encounter, both in the theory and practice of that art, will be easily conceived. If the blind must depend upon the exercise of their own powers for bread, we have already pointed out music as their easiest and most obvious province; but let it be remembered, that mediocrity in this art may prove the bitterest and most effectual curse which a parent can inflict upon his offspring: as it subjects them to every vicious impression or habit, which may be imbibed or contracted from the lowest and most abandoned of mankind. If your pupil, therefore, is not endowed with natural talents exquisitely proper both for the theory and practice of

this art, suffer him by no means to be initiated in it. If his natural genius favours your attempts, the piano, harp, or organ, are the most proper instruments for him to begin; because by these instruments he may be made more easily acquainted with the extent of musical scales, with the powers of harmony, with the relations of which it is constituted, and of course with the theory of his art. When he becomes a practical adept, tangible signs may be used, by which he may not only be enabled to read, but even to set music for himself. Such exercises will render him infinitely more accurate, both in his principles and practice, than he would otherwise be.

For the present article we acknowledge ourselves chiefly indebted to the Encyclopedia Britannica, a work of established merit; and we have even extended our limits, contrary to our professed design, beyond the *practical* part of science, because this article cannot fail to be interesting if it is known, as we are informed it is, to be the production of Dr. Blacklock. As an encouragement to the blind, or those who have blind children, we subjoin a few instances of extraordinary attainments in blind persons.

The most illustrious instance is the gentleman whom we have just had occasion to name, Dr. Thomas Blacklock; he was born in 1720, at Annan, in Dumfriesshire. His father was a bricklayer, and his mother the daughter of a dealer in cattle; both respectable in their characters and station. Before he was six years old he lost his sight by the smallpox, which prevented his father from executing his intention of bringing him up to some trade. He therefore encouraged the inclination he had early shown for books, by reading to amuse him; first, the small publications usually put into the hands of children, and afterward the works of our best authors, such as Milton, Prior, Pope, Addison, &c. His companions, attached to him by affection as well as compassion, were assiduous in reading to amuse and instruct him. By their aid he acquired some knowledge of Latin. Poetry was early his delight; and at twelve years of age he began to write poems himself, of considerable merit. He had attained the age of nineteen, when his indulgent father, whose kindness made a grateful and indelible impression on his mind, was killed by the fall of a malt kiln. This loss, severe to any one, but doubly so to one in his circumstances, and endued with his sensibility, led the way, however, to his receiving advantages which, perhaps, had his father lived, he might never have obtained. He had lived with his mother about a year after his father's death, when he began to be spoken of as a young man of uncommon genius; and several of his poetical productions were handed about, which enlarged the circle of his friends and acquaintance. Some of these being shown to Dr. Stevenson, of Edinburgh, that gentleman formed the benevolent design of carrying him to the metropolis, and giving him a classical education. He accordingly came to Edinburgh in 1741, and was enrolled as a student of divinity in the university, where he continued his studies till 1745; when, on account of the national disturbances, he returned to Dumfries, and resided with Mr. M'Murdo, his sister's husband. In 1746 he published a volume of his poems in 8vo. Upon his return to Edinburgh he obtained, among other literary acquaintance, that of the celebrated David Hume; who warmly interested himself in his favour, and assisted him in the publication, by subscription, of the quarto edition of his poems, which in 1754 had undergone a second edition in octavo. To the quarto edition Mr. Spence, professor of poetry at Oxford, from regard to the author, prefixed an ingenious account of his life and writings. About this time, while prosecuting his studies in the languages, and every other branch of science from which his want of sight did not preclude him, he became a complete master of the French tongue, by his intercourse with the family of provost Alexander, who had married a French lady. After passing the usual trials, he was licensed as a preacher by the presbytery of Dumfries, in 1759; and obtained no small reputation by the different sermons he preached, of which he left some volumes in manuscript. In 1762 he married Miss S. Johnston, daughter of Mr. Jos. Johnston, a respectable surgeon in Dumfries: a connection which proved the great blessing and comfort of his after life. A few days after, by lord Selkirk's interest, he obtained the royal presentation to the parish of Kirkcudbright: but the inhabitants, from various motives, opposing the presentation, the matter was compromised by settling a moderate annuity on Mr. Blacklock, upon his resigning his right to the living. With this slender provision he removed, in 1764, to Edinburgh; and adopted the plan of keeping young gentlemen as boarders, whose studies he could assist and superintend: which he continued until within four years of his death, when his weak state of health obliged him to give it up. In 1767 the university of Aberdeen conferred on him the degree of D. D. In summer 1791 he was seized by a feverish disorder, which, though at first it appeared slight, and never rose to a violent degree, overpowered his weak frame, and carried him off on the 3d of July, 1791, in his seventy-sixth year. A foreign author characterizes this extraordinary man in few words. "Blacklock," says he, "will appear to posterity a fabulous character; even now he is a prodigy."

Another no less striking instance is Dr. Nicolas Bacon, a blind gentleman, descended from the same family with the celebrated lord Verulam, was, in the city of Brussels, with high approbation created LL.D. He was deprived of sight at nine years of age, by an arrow from a crossbow whilst he was attempting to shoot it. When he had recovered his health, which had suffered by the shock, he pursued the same plan of education in which he had been engaged; and having heard that one Nicasius de Vourde, born blind, who lived toward the end of the 15th century, after having distinguished himself by his studies in the university of Louvain, took his degree as D. D. in that of Cologne, he resolved to make the same attempt; but the public, cursed with prejudices for which the meanest sensitive nature might blush, prejudices equally beneath the brutality and ignorance of the lowest animal instinct, treated his intention with ridicule: even the professors themselves were not far from being of the same sentiment; and they admitted him into their schools rather from an impression that it might amuse him, than become of any use to them. He had the good fortune, however, contrary to their expectations, to obtain the first places among his condisciples. It was then said, that such rapid advances might be made in the preliminary branches of his education, but would soon be effectually checked by studies of a more profound and abstracted nature. This, it seems, was repeated from school to school, through the

whole climax of his pursuits; and when, in the course of academical learning, it became necessary to study poetry, it was the general voice that all was over, and at length he had reached his ne plus ultra. But here he likewise disappointed their prejudices, and tanght them the immense difference between blindness of body and blindness of soul. After continuing his studies in learning and philosophy for two years more, he applied himself to law, took his degree in that science, commenced pleading counsellor or advocate in the council of Brabant, and had the pleasure of terminating almost every suit in which he was engaged to the satisfaction of his clients. The attainments of professor Saunderson are not less extraordinary, and yet as well established not only on the testimony of his pupils, but by his works. The following anecdotes of Dr. Moyes were not long ago presented to the Manchester society by Dr. G. Bew, and afterward published. "Dr. Henry Moyes, who occasionally read lectures on philosophical chymistry at Manchester, like Dr. Saunderson, the celebrated professor of Cambridge, lost his sight by the smallpox in his early infancy. He never recollected to have seen: 'but the first traces of memory I have,' says he, 'are in some confused ideas of the solar system.' He had the good fortune to be born in a country where learning of every kind is highly cultivated, and to be brought up in a family devoted to learning. Possessed of native genius, and ardent in his application, he made rapid advances in various departments of erudition, and not only acquired the fundamental principles of mechanics, music, and the languages, but likewise entered deeply into the investigation of the profounder sciences, and displayed an acute and general knowledge of geometry, optics, algebra, astronomy, chymistry, and, in short, of most of the branches of the Newtonian philosophy. Mechanical exercises were the favourite employments of his infant years. At a very early age he made himself acquainted with the use of edged tools so perfectly, that notwithstanding his entire blindness, he was able to make little windmills; and he even constructed a loom with his own hands, which still show the cicatrices of wounds he received in the execution of these juvenile exploits. By a most agreeable intimacy and frequent intercourse which I enjoyed with this accomplished blind gentleman, whilst he resided at Manchester, I had an opportunity of repeatedly observing the peculiar manner in which he arranged his ideas and acquired his information. Whenever he was introduced into company, I remarked that he continued for some time silent. The sound directed him to judge of the dimensions of the room, and the different voices of the number of persons that were present. His distinction in these respects was very accurate, and his memory so retentive that he seldom was mistaken. I have known him instantly recognise a person on first hearing him speak, though more than two years had elapsed since the time of their last meeting. He determined pretty nearly the stature of those he was speaking with, by the direction of their voices; and he made tolerable conjectures respecting their tempers and dispositions, by the manner in which they conducted their conversation. It must be observed that this gentleman's eyes were not totally insensible to intense light. The rays refracted through a prism, when sufficiently vivid, produced certain distinguishable effects on them. The red gave him a disagreeable sensation, which he compared to the touch of a saw. As the colours declined in violence, the harshness lessened, until the green afforded a sensation that was highly pleasing to him, and which he described as conveying an idea similar to what he felt in running his hand over smooth polished surfaces. Polished surfaces, meandering streams, and gentle declivities, were the figures by which he expressed his ideas of beauty. Rugged rocks, irregular points, and boisterous elements, furnished him with expressions for terror and disgust. He excelled in the charms of conversation; was happy in his allusions to visual objects; and discoursed on the nature, composition, and beauty of colours, with pertinence and precision. Dr. Moyes was a striking instance of the power the human soul possesses of finding resources of satisfaction, even under the most rigorous calamities. Though involved 'in ever during darkness,' and excluded from the charming views of silent or animated nature; though dependent on an undertaking for the means of his subsistence, the success of which was very precarious; in short, though destitute of other support than his genius, and under the mercenary protection of a person whose integrity he suspected; still Dr. Moyes was generally cheerful, and apparently happy. Indeed it must afford much pleasure to the feeling heart, to observe this hilarity of temper prevail almost universally with the blind." There are, in short, few sciences in which the blind have not distinguished themselves: even those whose acquisition seemed essentially to depend upon vision, have at last yielded to genius and industry, though deprived of that advantage. Sculpture is not the most practicable art for a blind man; yet there are instances of persons who have taken the figure of a face by the touch, and moulded it in wax with the utmost exactness; as was the case of the blind sculptor mentioned by De Piles, who thus took the likeness of the duke de Bracciano in a dark cellar, and made a marble statue of king Charles I. with great elegance and justness. In music, there are, at present, living instances how far the blind may proceed. In former periods we shall find illustrious examples how amply nature has capacitated the blind to excel, both in the scientific and practical departments of that enchanting art.

Dr. Bew, in the Transactions of the Manchester Society, above quoted, mentions an instance, which would be beyond belief if we had it not on such respectable authority. "John Metcalf, a native of the neighbourhood of Manchester, where he is well known, became blind at a very early age, so as to be entirely unconscious of light and its various effects. This man passed the younger part of his life as a waggoner, and occasionally as a guide in intricate roads during the night, or when the tracks were covered with snow. Strange as this may appear to those who can see, the employment he has since undertaken is still more extraordinary: it is one of the last to which we could suppose a blind man would ever turn his attention. His present occupation is that of a projector and surveyor of highways in difficult and mountainous parts. With the assistance only of a long staff, I have several times met this man traversing the roads, ascending precipices, exploring vallies, and investigating their several extents, forms, and situations, so as to answer his designs in the best manner. The plans which he designs, and the estimates he makes, are done in a manner peculiar to himself, and which he cannot well convey the meaning of to

others. His abilities in this respect are nevertheless so great, that he finds constant employment. Most of the roads over the Peak in Derbyshire have been altered by his directions, particularly those in the vicinity of Buxton; and he is at this time constructing a new one betwixt Wilmeslow and Congleton, with a view to open a communication to the great London road, without being obliged to pass over the mountains."

Bishop Burnett, in his Letters, mentions a blind lady, whom he saw at Geneva, who lost her sight at one year old, yet was eminently skilled in most sciences, ancient and modern. She spoke French, German, Italian, and Latin; and played exquisitely on several musical instruments. She wrote very legibly with a crayon. The means by which her father taught her to write was, by having letters carved in wood; and by feeling them she acquired a correct idea of their form. The bishop saw her write, which she did very fast, aided only by a machine which held the paper, and kept her always in line.

In the Annual Register for 1762, we have a similar account. "A young gentlewoman of a good family in France, now in her 18th year, lost her sight when only two years old, her mother having been advised to lay some pigeons' blood on her eyes, to preserve them in the smallpox; whereas, so far from answering the end, it ate into them. Nature, however, may be said to have compensated for the unhappy mistake, by beauty of person, sweetness of temper, vivacity of genius, quickness of conception, and many talents, which certainly much alleviate her misfortune. She plays at cards with the same readiness as others of the party. She first prepares the packs allotted to her, by pricking them in several parts; yet so imperceptibly, that the closest inspection can scarcely discern her indexes. She sorts the suits, and arranges the cards in their proper sequence, with the same precision, and nearly the same facility, as those who have their sight. All she requires of those who play with her is to name every card as it is played; and these she retains so exactly, that she frequently performs some notable strokes, such as show a great combination and strong memory. The most wonderful circumstance is, that she should have learned to read and write; but even this is readily believed on knowing her method. In writing to her, no ink is used, but the letters are pricked down on the paper; and by the delicacy of her touch, feeling each letter, she follows them successively, and reads every word with her finger ends. She herself in writing makes use of a pencil, as she could not know when her pen was dry; her guide on the paper is a small thin ruler, and of the breadth of her writing. On finishing a letter, she wets it, so as to fix the traces of her pencil, that they are not obscured or effaced; then proceeds to fold and seal it, and write the direction: all by her own address, and without the assistance of any other person. Her writing is very straight, well cut, and the spelling no less correct. To teach this singular mechanism, the indefatigable cares of her affectionate mother were long employed: who accustomed her daughter to feel letters cut in cards or pasteboard; brought her to distinguish an A from a B, and thus the whole alphabet, and afterward to spell words; then by the remembrance of the shape of the letters, to delineate them on paper; and lastly, to arrange them so as to form words and sentences. She has learned to play on the guitar; and has even contrived a way of pricking down the tunes, as an assistance to her memory. So delicate are her organs, that in singing a tune, though new to her, she is able to name the notes. In figured dances she acquits herself extremely well, and in a minuet with inimitable ease and gracefulness. As for the works of her sex, she has a masterly hand: she sews and hems perfectly well; and in all her works she threads the needles for herself, however small. By the watch, her touch never fails telling her exactly the hour and minute."

These instances afford the happiest encouragement both to those who labour under this misfortune, not to despair of attaining by perseverance the intellectual accomplishments; and a striking admonition to parents not to increase, by their negligence, a calamity to which a darling child may be subjected by the dispensation of Providence. Some benevolent institutions have been lately established for the employment and instruction of the blind poor; and we have little doubt that the views of their projectors will, in many cases, be fully answered.

BLINK *of the ice*, in sea language, denotes that bright appearance produced by the ice near the horizon; and perceptible, in approaching the ice, long before it is itself seen.

BLISTER, in medicine, a thin bladder containing a watery humour, whether occasioned by burns, and the like accidents, or by vesicatories laid on different parts of the body for that purpose.

Cantharides, or Spanish flies, applied in the form of a plaster, are chiefly used with this intention. See MATERIA MEDICA.

BLITUM, the *blite*, or *strawberry spinach*, a genus of the digynia order and monandria class of plants, and in the natural method ranking in the 12th order, holoraceæ. The calyx is trifid; no petals; the seed is one, included in a berry shaped calyx. There are four species, *viz.*

1. Blitum capitatum, with flowers in clustered heads at the joints and crown of the stalks, is a native of Spain and Portugal, but has been long preserved in the British gardens for the beauty of its fruit. It is an annual plant, with leaves somewhat like those of the spinach; the stalk rises two feet and a half high; the upper part of the stalk has flowers coming out in small heads at every joint, and is terminated by a little cluster of the same; after the flowers are past, the heads swell to the size of wood strawberries, and when ripe have the same appearance, but are not eatable; they are full of purple juice, which stains the hands of those who bruise them of a deep purple colour.

2. Blitum tartaricum, with triangular acutely indented leaves, is a native of Tartary. It rises to near three feet high; the flowers come out from the sides of the stalks, but are smaller than those of the capitatum, as is also the fruit.

3. Blitum virgatum, with small heads growing from the sides of the stalks, is a native of the south of France and Italy. It seldom grows more than a foot high; the leaves are of the same shape with those of the capitatum, but smaller. The flowers are produced at the wings of the leaves, almost the length of the stalk; they are smaller, and not so deeply coloured as the first.

4. Blitum chenopodioides, is a low plant, a native of Tartary.

All these species being annual, must be propagated by seeds, and are very hardy.

BLOCKS, on ship board, is the usual name for what we call pulleys at land. They are thick pieces of wood, some with three, four, or five shivers in them, through which all the running ropes run. Blocks, whether single or double, are distinguished and called by the names of the ropes they carry, and the uses they serve for. Double blocks are used when there is occasion for much strength, because they will purchase with more ease than single blocks, though much slower.

Block and block, is a phrase signifying that two blocks meet, in haling any tackle or halliard, having such blocks belonging to them. Fish block is hung in a notch at the end of the davit. It serves to hale up the flukes of the anchor at the ship's prow. Snatch block is a great block with a shiver in it, and a notch cut through one of its cheeks, for the more readily receiving of any rope; as by this notch the middle part of a rope may be reeved into a block, without passing it endwise. It is commonly fastened with a strap about the mainmast, close to the upper deck, and is chiefly used for the fall of the winding tackle, which is reeved into this block, and then brought to the capstan.

Blocks now used in the navy are made in the Portsmouth yard, by means of machinery, which has lately been erected for the purpose, and which performs the several operations from the rough timber to the perfect block in the completest manner possible. But as the machinery is so complicated, as would require a dozen pages of explanation, to render it intelligible; whilst it could interest, perhaps, but a small portion of our readers; we have concluded to omit it, to make room for more useful information.

Block *engraving*. See Engraving.

BLOOD, *sanguis*, a red liquor, circulating through the arteries, veins, and other vessels of animal bodies; and serving for the support of life, and nourishment of all their parts. See Anatomy, and Physiology.

BLOOM, a mass of iron after having undergone the first hammering, called blomary.

BLOSSOM, denotes the flowers of plants, but more especially of fruit trees.

BLOW PIPE, or *blowing pipe*, a hollow tube, used by several artificers: as enamellers, glass makers, jewellers, &c. It is a wind instrument for the purpose of increasing the heat of a candle or lamp, as common bellows are employed for raising the temperature of a fire or furnace. The blow pipe is of great use in practical chymistry. See Chymistry.

BLOWING *of glass*, one of the methods of forming the divers kinds of works in the glass manufacture.

It is performed by dipping the point of an iron blowing pipe in the melted glass, and blowing through it with the mouth, according to the circumstances of the glass to be blown. See Glass.

Blowing *of tin*, denotes the melting its ore, after being first burnt to destroy the mundic.

BLUBBER, denotes the fat of whales and other large sea animals, of which is made train oil.

The blubber is the *adeps* of the animal: it lies under the skin, and over the muscular flesh: it is about six inches in thickness, but about the under lip it is two or three feet thick. The quantity yielded by a good sized whale amounts to from forty to eighty hundred weight, or even more. The use of the blubber to the fish seems to be partly to poise the body, and partly to keep off the water at some distance from the blood; and thus it acts as clothing to keep the fish warm.

BLUE, *painter's*, is made differently, according to the different kinds of painting. In limning, fresco, and miniature, they use indifferently ultramarine, blue ashes, and smalt: these are their natural blues, excepting the last, which is partly natural, and partly artificial.

In oil and miniature they also use indigo prepared, as also a factitious ultramarine.

Enamellers and painters upon glass have also blues proper to themselves, each preparing them after their own manner.

Blue, *turnsole*, is used in painting on wood, and is made of the seed of that plant: the way of preparing it is, to boil four ounces of turnsole in a pint and a half of water, in which lime has been slacked.

Blue, *Flanders*, is a colour bordering on green, and seldom used but in landscapes.

Bluing *of metals* is performed by heating them in the fire till they assume a blue colour; particularly practised by gilders, who blue their metals before they apply the gold and silver leaf.

Blue, *to dye skins*. Boil elder berries or dwarf elder, then smear and wash the skins therewith, and wring them out: then boil the berries as before, in a solution of alum water, and wet the skins in the same manner once or twice; dry them, and they will be very blue.

A Blue *for painting or staining of glass*. Take fine white sand twelve ounces, zaffer and minium of each three ounces; reduce them to a fine powder in a bell metal mortar, then putting the powder into a very strong crucible, cover it and lute it well, and, being dry, calcine it over a quick fire for an hour; take out the matter and pound it: then to sixteen ounces of this powder add fourteen of nitre powder; mix them well together, and put them into the crucible again: cover and lute it, and calcine for two hours on a very strong fire.

Blue, *Prussian*. This blue is next to ultramarine for beauty, if it is used in oil: this colour does not grind well in water.

Blue bice is a colour of good brightness, next to Prussian blue, and also a colour of a body, and will flow pretty well in the pencil..

Blue, *Saunders*, is also of very good use, and may serve as a shade to ultramarine, or the blue bice, where the shades are not required to be very deep; and is of itself a pleasant blue, to be laid between the light and shades of such a flower as is of a mazarine blue.

Blue, *a fine one from Mr. Boyle*. Take the blue leaves of rue, and beat them a little in a stone mortar with a wooden pestle; then put them in water, juice and all, for fourteen days or more, washing them every day till they are rotten; and at last beat them and the water together till they become a pulp, and let them dry in the sun. This is a fine blue for shading.

Blue, *Indigo*. This makes the strongest shade for blues, and is of a soft warm colour, when it has been well ground, and washed with gum water, by means of a stone and a muller.

BLUE, *Lacmus*, or *Litmus*. This is a beautiful blue, and will run in a pen as free as ink. It is made of lacmus, and prepared thus; take an ounce of lacmus, and boil it in a pint of small beer wort, till the colour is as strong as you would have it; then pour off the liquor into a gallipot, and let it cool for use. This affords a beautiful colour, has extraordinary effects, and is a holding colour; if it is touched with aquafortis, it immediately changes to a fine crimson, little inferior to carmine.

BLUE, *Japan*. Take gum water, what quantity you please, and white lead a sufficient quantity, grind them well on a porphyry; then take isinglass size, what quantity you please, of the finest and best smalt a sufficient quantity, mix them well; to which add of your white lead before ground, so much as may give it a sufficient body; mix all these together to the consistence of a paint.

BLUENESS *of the skies*. Sir Isaac Newton observes, that all the vapours, when they begin to condense and coalesce into natural particles, become first of such a bigness, as to reflect the azure rays, before they can constitute clouds, or any other colour.

But Mr. Melville supposes, that the clouds only reflect and transmit the sun's light; and that, according to their different altitudes, they may assume all the variety of colours at sunrising and setting, by barely reflecting the sun's incident light, as they receive it through a shorter or longer tract of air; and the change is produced in the sun's rays by the quantity of air through which they pass, from white to yellow, from yellow to orange, and lastly to red.

BLUFF HEAD, among sailors. A ship is said to be bluff headed that has an upright stern.

BOA, a genus of serpents belonging to the order of amphibia; the generic character is, scuta, or undivided plates, both on the abdomen and beneath the tail.

This genus of serpents is remarkable for the vast and almost unlimited size of some of the principal species, which in India, Africa, and South America, are occasionally found of not less than twenty, thirty, and even thirty-five feet in length, and of a strength so prodigious as to be able to destroy cattle, deer, &c. by twisting round them in such a manner as to crush them to death by continued pressure, after which they swallow them in a very gradual manner; and when thus gorged with their prey, become almost torpid with repletion, and if discovered in this state, may without much difficulty be destroyed by shooting or other methods. There is reason to suppose that these gigantic serpents are become less common now than some centuries backward.

There are nineteen species, *viz.*

1. Boa constrictor. Of all the larger boæ this is most conspicuous, and is at once pre-eminent from superiority of size and beauty of colour: in this respect indeed it appears to be subject to considerable variation from age, sex, and climate, but may be distinguished in every state from the rest of its tribe by the peculiar disposition of its variegations. The ground colour of the whole animal, in the younger specimens, is a yellowish gray, and sometimes even a bright yellow; on which is disposed along the whole length of the back a series of large, chain like, reddish brown, and sometimes perfectly red variegations, leaving large open oval spaces of the ground colour at regular intervals; between these larger marks are disposed many smaller ones of uncertain forms, and more or less numerous in different parts.

The boa constrictor is a native of Africa, India, the larger Indian islands, and South America, where it chiefly resides in the most retired situations in woody and marshy regions.

It was, in all probability, an enormous specimen of this very serpent that once diffused so violent a terror amongst the most valiant of mankind, and threw a whole Roman army into dismay. Historians relate this surprising event in terms of considerable luxuriance. Valerius Maximus thus mentions it from Livy, in one of the lost books of whose history it was related more at large.

"And since we are on the subject of uncommon phenomena, we may here mention the serpent so eloquently and accurately recorded by Livy; who says, that near the river Bagrada in Africa, a snake was seen of so enormous a magnitude as to prevent the army of Attilius Regulus from the use of the river; and after snatching up several soldiers with its enormous mouth, and devouring them, and killing several more by striking and squeezing them with the spires of its tail, was at length destroyed by assailing it with all the force of military engines and showers of stones, after it had withstood the attack of their spears and darts: that it was regarded by the whole army as a more formidable enemy than even Carthage itself: and that the whole adjacent region being tainted with the pestilential effluvia proceeding from its remains, and the waters with its blood, the Roman army was obliged to remove its station: he also adds, that the skin of the monster, measuring 120 feet in length, was sent to Rome as a trophy."

The flesh of this serpent is eaten by the Indians and negroes of Africa, and they make its skin into garments. See Plate XV. Nat. Hist. fig. 50.

2. Boa scytale, or spotted. The spotted boa is sometimes scarcely inferior in size to the constrictor, and is of similar manners, destroying, like that animal, goats, sheep, deer, &c. It is described as being generally of a gray or glaucous colour, marked with large orbicular black spots on the back; and with smaller ones of similar form, but with white centres, on the sides; while on the abdomen are scattered several oblong spots and marks, interspersed with smaller specks and variegations. It is a native of several parts of South America, and, like other large snakes, is occasionally eaten by the Indians.

3. Boa cenchris, or ringed. This also grows to a large size, though not equal to either of the former species, from which, as well as from most others, it may be easily distinguished by the regular distribution of its colours; the general cast being ferruginous, darkest on the back, where it is marked by a continued series of very large blackish circles from head to tail; while along the sides are interspersed several kidney shaped blackish spots with white centres: the head is a lengthened form, and is marked by a black longitudinal and two lateral bands. This animal is a native of South America.

4. Boa enydris, or water. This species, according to Linnæus, is variegated with different shades of gray; the teeth in the lower jaw are longer than usual in this genus; the number of abdominal scuta is 270, and of the subcaudal ones 105.

5. Boa orphryas, or brown, mentioned by Linnæus from a specimen in the museum of Degeer: has the general habit

of the B. constrictor, but is of a dark or dusky colour, and has 231 abdominal and 84 subcaudal scuta.

6. Boa canina, a highly beautiful snake: measuring about four feet in length, and being of moderate size or thickness in proportion: the head is large, and shaped like that of a dog; the colour of the whole animal on the upper parts is a most beautiful Saxon green, with several short, undulating, transverse white bars down the back, the edges of which are of a deeper or stronger green than the ground colour of the body: the under or abdominal part is white. This species is a native of South America. In the British Museum is an elegant specimen.

7. Boa regia is, in the form of its head and the general shape of the body, most allied to the canina and phrygia. In its colour it appears to vary, the ground colour being white, but the variegations sometimes dusky or chesnut, and sometimes of a most elegant orange red, accompanied by a tinge of blossom colour on the lighter parts. The head is covered in front with large scales: the tail is extremely short, and tapers suddenly.

8. Boa phrygia. Among the whole serpent tribe it may be doubted whether there exists a species more truly elegant than the present. Its general size seems to be nearly that of the boa canina, but its length is rather greater in proportion: the ground colour of the whole animal is white, with a very slight cast of yellowish brown on the back, while along the whole upper part is disposed a continued series of black variegations, so conducted as to bear a striking resemblance to an embroidery in needle work: the head is of the same form with that of the boa canina, and marked by three narrow black streaks, which, running along the top of the head and the cheeks, join with the embroidered pattern of the back.

9. Boa hortulana is of moderate size, measuring only a few feet in length, and being of a slender form; has obtained its Linnæan title from the singular variegations on the head, which are of a blackish brown, on a pale ferruginous or yellowish ground, and in some degree represent the form of a parterre in an old fashioned garden: the variegations on the body are of similar colour, and are disposed into large circular, and sometimes angular patches on the sides. See Plate XV. Nat. Hist. fig. 51.

10. Boa murina is a middle sized species, measuring about two feet and a half or three feet in length, and being of a moderately thick form: the colour of the whole upper part is gray or bluish brown, with several moderately large round black spots dispersed in a somewhat irregular manner along the back and sides: the head is marked on each side by two longitudinal black stripes: this species is said to feed principally on rats, and to be found in South America.

11. Boa crotaline is a native of Surinam, and is a large species, marked on the back by a chain of black rhomboid spots, and is furnished with very large and strong fangs.

12. Boa fasciata. It is to Dr. Patrick Russel that we owe the knowledge of this remarkable species, which is a native of India, and is said to be most frequent in the country of Bengal. It is of a yellow colour, marked with pretty numerous dusky blue transverse bands, continued at equal distances: the head is rather small, and covered in front with large scales: the body is of a trigonal form, the sides sloping very considerably: the whole length of the animal is something more than five feet; the diameter, in the thickest part, being nearly five inches: the length of the tail five inches only, and its termination rather obtuse.

This snake is among the number of poisonous species, and its bite is considered by the Indians as inevitably fatal. A specimen was brought to Dr. Russel in the month of November, 1788, in an apparently weak and languid state, having been bruised in taking. Being set at liberty in a room, it crept slowly toward an obscure corner; where a chicken being presented to him he took no particular notice of it, and even suffered the bird to stand on his back. As he showed no disposition to bite, his jaws were forcibly opened, and the thigh of the chicken being placed between them, the mouth was so closed over it as to oblige the fangs to act. The bird, when disengaged, showed immediate symptoms of poison, and after several ineffectual efforts to rise, rested with the beak on the ground, the head being seized with trembling. In the space of twenty minutes it lay down on one side, and convulsions soon supervening, it expired within twenty-six minutes from the bite.

13. Boa viperina is also an Indian species, first described in the work of Dr. Russel. It is about a foot and a half in length and of a moderately deep brown colour; the back being marked throughout the whole length by a broad undulating black band, with a narrow yellowish white margin, while along the sides runs a row of somewhat irregular roundish black spots: the under part of the animal is of a pearl colour. The head is hardly broader than the neck, oblong, roundish, depressed, subtruncate, and covered with small scales: the teeth are small and numerous, and as there is a marginal row in the upper jaw, there are of course no fangs: the trunk or body is round, of nearly equal thickness, and coated with small, orbicular, close set, carinated scales.

This snake, Dr. Russel informs us, is said to produce by its bite a slow wasting of the fingers and toes, similar to what happens in some leprous cases. A living specimen, however, which he obtained in Dec. 1788, from Ganjam, enabled him to make some experiments with it on chickens; but though it arrived in excellent order, and bit ferociously, the bite was followed by no symptoms of poison.

14. Boa lineata, geedi paragoodoo, or cobra monil, is of an extremely dark blue colour, so as to appear almost black in certain lights, and is marked throughout the whole length of the upper part by several transverse curved and dotted white lines at somewhat unequal distances. The natives of India, who generally exaggerate the noxious character of their serpents, assert that the bite of this animal produces immediate death. The experiments of Dr. Russel, however, prove that it is seldom fatal to chickens in less than half an hour, and to dogs in less than an hour and ten minutes. Its poison was also observed to cause less violent convulsions in the animals infected by it than that of the cobra de capello, and another highly poisonous Indian snake called katuka rekula poda; but produced a greater degree of stupor.

15. Boa horatta is a small species, measuring only about fifteen inches in length. Its colour is a dark brown, with a row of spots on the ridge of the back, from the neck to the end of the tail, varying a little in size and figure, but all of a dull yellowish colour edged with black. The fangs

or poisoning organs of this snake show it to be noxious; but in what degree could not be ascertained by Dr. Russel, who could not meet with a living subject to make the necessary experiments with. It is reported, however, to be one of the most fatal of serpents.

16. Boa siamese, a small species, but very long in proportion to its breadth; the circumference of the body being scarcely more than an inch and a half, and the length from two to three feet: the head shaped like that of the boa canina: the colour of the whole animal pale yellow above, with pretty numerous transverse broken bars of white, with black or deep brown edges; the abdomen yellow. This species is said to be a native of the East Indies, and particularly of the kingdom of Siam.

17. Boa contorix, a small species, seldom exceeding the length of about fifteen inches: head large, with the cheeks swelling out like those of vipers; the nose turning up, like that of a hog: the body very thick toward the head: colour pale brown, with several large black spots or patches disposed along the back and sides. This species is a native of North America, and is of a poisonous nature: it is slow in its motions, and has a malevolent aspect; the tail is nearly a third of the length of the whole animal.

18. Boa palpebrosa. Length about fifteen inches: head rather large, and covered in front with large scales: eyebrows remarkably prominent; body thick in proportion to its length: colour pearly gray above, with obscure transverse dusky or bluish undulations; beneath pale yellow brown: native country unknown.

19. Boa annulata. This is rather a small species, measuring about two feet in length: in its general appearance it is allied to the boa hortulana; but the back is marked with large round black spots, almost encircled by a narrow zone of the same colour. It is a native of South America.

BOAR. See Sus.

BOARD, among seamen. To go aboard, signifies to go into the ship. To slip by the board, is to slip down by the ship's side. Board and board, is when two ships come so near as to touch one another, or when they lie side by side. To make a board, is to turn to windward; and the longer your boards are, the more you work into the wind. To board it up, is to beat it up sometimes upon one tack, and sometimes upon another. She makes a good board, that is, the ship advances much at one tack. The weather board, is that side of the ship which is to windward.

BOAT, a small open vessel, commonly wrought by rowing. The structure, and even the names of boats, are different, according to the different uses they are designed for, and the places where they are to be used.

The several boats and their names are as follow: a long boat, a jolly boat, a skiff, a pinnace, a water boat, a yaul; the preceding six are boats for ships. Other boats are, a gondola, a Greenland boat, a Bermudas boat, a ballon of Siam, a horse boat, a periaga, a pleasure boat, a ponton, a canoe, a crucle, a curry curry, a deal hooker, a felucca, a ferry boat, a praw, a flying praw, a punt, a tilt boat, a tod boat, a well boat, a wherry, &c.

The boats or wherries plying about London, are either scullers, wrought by a single person, with two oars; or oars, wrought by two persons, with each an oar. All boats rowed with more than four oars above or below London bridge, are forfeited.

BOAT, *life*, a boat invented by Mr. Henry Greathead, of South Shields, for the purpose of preserving the lives of shipwrecked persons. The following circumstance gave rise to this invention:

In September, 1789, the ship Adventure, of Newcastle, was stranded on the Herd sand, on the south side of Tynemouth haven, in the midst of tremendous breakers; and all the crew dropped from the rigging one by one, in the presence of thousands of spectators; not one of whom could be prevailed upon, by any reward, to venture out to her assistance, in any boat or coble of the common construction.

On this occasion the gentlemen of South Shields called a meeting of the inhabitants, at which a committee was appointed, and premiums were offered for plans of a boat which should be the best calculated to brave the dangers of the sea, particularly of broken water.

Many proposals were offered; but the preference was unanimously given to that of Mr. Greathead, who was immediately directed to build a boat at the expense of the committee.

This boat went off on the 30th of January, 1790; and so well has it answered, and indeed exceeded, every expectation, in the most tremendous broken sea, that since that time, not fewer than two hundred lives have been saved at the entrance of the Tyne alone, which otherwise must have been lost; and in no instance has it ever failed.

The principle of this boat appears to have been suggested to Mr. Greathead by the following simple fact: Take a spheroid, and divide it into quarters; each quarter is elliptical, and nearly resembles the half of a wooden bowl, having a curvature with projecting ends; this thrown into the sea or broken water, cannot be upset, or lie with the bottom upward.

The length of the boat is thirty feet; the breadth ten feet; the depth, from the top of the gunwale to the lower part of the keel in midships, three feet three inches; from the gunwale to the platform, within, two feet four inches; from the top of the stems, both ends being similar, to the horizontal line of the bottom of the keel, five feet nine inches. The keel is a plank of three inches thick, of a proportionate breadth in midships, narrowing gradually toward the ends, to the breadth of the stems at the bottom, and forming a great convexity downward. The stems are segments of a circle, with considerable *rakes*. The bottom section, to the floor heads, is a curve fore and aft, with the sweep of the keel. The floor timber has a small rise curving from the keel to the floor heads. A bilge plank is wrought in on each side, next the floor heads, with a double rabbit or groove, of a similar thickness with the keel; and, on the outside of this, are fixed two bilge trees, corresponding nearly with the level of the keel. The ends of the bottom section form that fine kind of entrance observable in the lower part of the bow of the fishing boat called a *coble*, much used in the north. From this part to the top of the stem it is more elliptical, forming a considerable projection. The sides, from the floor heads to the top of the gunwale, flaunch off on each side, in proportion to above half the breadth of the floor. The breadth is continued far forward toward the ends, leaving a sufficient length of straight side at the top. The sheer is regular along the straight side, and more elevated toward the ends. The gunwale fixed to the outside is three

inches thick. The sides, from the under part of the gunwale, along the whole length of the regular sheer, extending twenty-one feet six inches, are cased with layers of cork to the depth of sixteen inches downward; and the thickness of this casing of cork being four inches, it projects at the top a little without the gunwale. The cork, on the outside, is secured with thin plates or slips of copper, and the boat is fastened with copper nails. The thwarts, or seats, are five in number, *double banked:* consequently the boat may be rowed with ten oars. The thwarts are firmly stanchioned. The side oars are short, with iron tholes and rope grommets, so that the rower can pull either way. The boat is steered with an oar at each end; and the steering oar is one third longer than the rowing oar. The platform placed at the bottom, within the boat, is horizontal, the length of the midships, and elevated at the ends for the convenience of the steersman, to give him a greater power with the oar. The internal part of the boat next the sides, from the under part of the thwarts down to the platform, is cased with cork; the whole quantity of which, affixed to the life boat, is nearly seven hundred weight. The cork indisputably contributes much to the buoyancy of the boat, is a good defence in going alongside a vessel, and is of principal use in keeping the boat in an erect position in the sea, or rather for giving her a very lively and quick disposition to recover from any sudden *cant* or *lurch* which she may receive from the stroke of a heavy wave. But, exclusively of the cork, the admirable construction of this boat gives it a decided pre-eminence. The ends being similar, the boat can be rowed either way; and this peculiarity of form assists her in rising over the waves. The curvature of the keel and bottom facilitates her movement in turning, and contributes to the ease of the steerage, as a single stroke of the steering oar has an immediate effect, the boat moving as upon a centre. The fine entrance below is of use in dividing the waves, when rowing against them; and, combined with the convexity of the bottom, and the elliptical form of the stem, admits her to rise with wonderful buoyancy in a high sea, and to launch forward with rapidity, without shipping any water, when a common boat would be in danger of being filled. The flaunching or spreading form of the boat, from her floor heads to the gunwale, gives her a considerable bearing; and the continuation of the breadth, well forward, is a great support to her in the sea; and it has been found by experience that boats of this construction are the best sea boats for rowing against turbulent waves. The internal shallowness of the boat from the gunwale down to the platform, the convexity of the form, and the bulk of cork within, leave a very diminished space for the water to occupy; so that the life boat, when filled with water, contains a considerable less quantity than the common boat, and is in no danger either of sinking or overturning. It may be presumed by some, that in cases of high wind, agitated sea, and broken waves, a boat of such a bulk could not prevail against them by the force of oars; but the life boat, from her peculiar form, may be rowed ahead, when the attempt in other boats would fail. Boats of the common form, adapted for speed, are of course put in motion with a small power; but for want of buoyancy and bearing, are overrun by the waves, and sunk when impelled against them; and boats constructed for burthen meet with too much resistance from the wind and sea when opposed to them, and cannot in such cases be rowed from the shore to a ship in distress.

Mr. Greathead gives the following instructions for the management of the life boat:

The boats in general of this description, are painted white on the outside; this colour more immediately engaging the eye of the spectator when rising from the hollow of the sea than any other. The bottom of the boat is at first varnished, which will take paint afterward, for the more minute inspection of purchasers. The oars she is equipped with are made of fir of the best quality; having found by experience that a rove ash oar, that will dress clean and light, is too pliant among the breakers; and when made strong and heavy, from rowing double banked, the purchase being short, sooner exhausts the rower; which renders the fir oar, when made stiff, preferable.

In the management of the boat she requires twelve men to work her: that is, five men on each side rowing double banked, with an oar slung over an iron thole, with a grommet, as provided, so as to enable the rower to pull either way, and one man at each end to steer her, and to be ready at the opposite end to take the steer oar when wanted. As, from the construction of the boat, she is always in a position to be rowed either way, without turning the boat: when manned, the person who steers her should be well acquainted with the course of the tides, in order to take every possible advantage: the best method, if the direction will admit of it, is to head the sea. The steersman should keep his eye fixed upon the wave or breaker, and encourage the rowers to give way as the boat rises to it; being then aided by the force of the oars, she launches over it with vast rapidity, without shipping any water. It is necessary to observe, that there is often a strong reflux of sea occasioned by the stranded wrecks, which requires both despatch and care in the people employed that the boat be not damaged. When the wreck is reached, if the wind blows to the land, the boat will come in shore without any other effort than steering.

BOATSWAIN, a ship officer, to whom is committed the charge of all the tacklings, sails and rigging, ropes, cables, anchors, flags, pendants, &c. He is also to take care of the long boat and its furniture, and to steer her either by himself or his mate. He calls out the several gangs and companies aboard, to the due execution of their watches, works, spells, &c. He is likewise provost marshal, who sees and punishes all offenders sentenced by the captain, or a court marshal of the fleet.

BOB, or *ball*, is a metallic weight, attached to the lower extremity of a pendulum rod, by means of a tapped adjusting nut, at such a distance from the point of suspension as the time of a given vibration requires.

BOBBIN, a small piece of wood turned in the form of a cylinder, with a little border jutting out at each end, bored through to receive a small iron pivot. It serves to spin with the spinning wheel; or to wind thread, worsted, hair, cotton, silk, gold, and silver.

BOCARDO, among logicians, the fifth mode of the third figure of syllogisms, in which the middle proposition is an universal affirmative, and the first and last particular negatives, thus:

Bo Some sickly persons are not students;
CAR Every sickly person is pale;
DO Therefore some persons are pale that are not students.

BOCCONIA, *greater tree celandine*: a genus of the monogynia order, and dodecandria class of plants, and in the natural method ranking under the 27th order, rhœadeæ. The calyx is diphyllous; there is no corolla; the stylus is bifid; the berry is dry, and monospermous. Of this genus there is but one known species, *viz.*

Bocconia *frutescens*, which is esteemed for the beauty of its large foliage. It is very common in Jamaica and the warm parts of America, where it grows to the height of 10 or 12 feet, having a straight trunk as large as a man's arm, and covered with a white smooth bark. At the top it divides into several branches, on which the leaves are placed alternately. These leaves are 8 or 9 inches long, and 5 or 6 broad; and are of a fine glaucous colour. The whole plant abounds with a yellow juice of an acrid nature; so that it is used by the inhabitants of America to take off warts and spots from the eyes. The singular beauty of this plant renders it worthy of a place in every curious collection: and it seems the Indians are very fond of it; for Hernandez tells us, their kings used to plant it in their gardens. It is propagated by seeds from America, and must always be kept in a stove.

BOCK LAND, in the Saxons' time, is what we now call freehold lands, held by the better sort of persons by charter or deed in writing; by which name it was distinguished from folkland, or copyhold land, holden by the common people without writing.

BODY, in physics, an extended solid substance, of itself utterly passive and inactive, indifferent either to motion or rest; but capable of any sort of motion, and of all figures and forms.

Descent of Bodies. Heavy bodies, in an unresisting medium, fall with an uniformly accelerated motion; whence the spaces descended are in the duplicate ratio of the times and velocity, and increase according to the uneven numbers 1, 3, 5, &c. The times and velocities are in a subduplicate ratio of the spaces. The velocity of descending bodies is in proportion to the times from the beginning of their fall; and the spaces described by a falling body, are as the squares of the times from the beginning of their fall. See Mechanics.

Body, in geometry, the regular bodies, or those which have all their angles and sides similar and equal, are five, *viz.* tetrahedron, octahedron, dodecahedron, icosahedron, and the cube.

Body, among painters, as to bear a body, a term signifying that the colours are of such a nature as to be capable of being ground so fine, and mixing with the oil so entirely, as to seem only a very thick oil of the same colour.

BOEBERA *Chrysanthemoides*, in botany, a plant of the syngenesia, superflua class and order of plants: the calyx is duplex; corolla radiated, luted, annual, a native of Missouri. (*a.*)

BOEHMERIA, a genus of the monoecia tetrandria class and order. The essential character is, male, calyx four parted; corolla none. Female, calyx none; germ obovate; style single; seed single, compressed.

There are five species, natives of America and the West Indies.

BOERHAAVIA, a genus of the monogynia order, and monandria class of plants. There is no calyx; the corolla is monopetalous, campanulated, and plaited; and the seed is one, naked and below. There are seven species, all natives of the Indies. Some of these plants rise 5 or 6 feet high, but most of them only 18 inches or 2 feet. They bear flowers of a yellow or red colour.

BOG properly signifies a quagmire, covered indeed with grass, but not solid enough to support the weight of the body; in which sense it differs only from marshes or fens, as a part from the whole: some even restrain the term bog to quagmires pent up between two hills; whereas fens lie in champaign and low countries, where the descent is very small. To drain boggy lands, a good method is, to make trenches of a sufficient depth to carry off the moisture; and if these are partly filled up with rough stones and then covered with thorn bushes and straw to keep the earth from filling up their interstices, a stratum of good earth and turf may be laid over all; the cavities among the stones will give passage to the water, and the turf will grow at top as if nothing had been done.

BOILING, or *ebullition*, in physics, the agitation of a fluid body, arising from the application of fire, &c.

It has been proved that all fluidity is the effect of a certain quantity of caloric, or the matter of heat, absorbed by a body in passing from a solid to a fluid state, as is shown in the melting of ice, tallow, wax, &c. Boiling is the act of a body passing from a fluid state to that of vapour, occasioned by a further absorption of caloric.

If the heat is applied to the bottom of the vessel containing the liquids, as is usually the case, after the whole liquid has acquired a certain temperature, those particles of it which are next the bottom, become elastic, and rise up, as they are formed, through the liquid, like air bubbles, and throw the whole into a violent agitation. The liquid is then said to boil.

A pleasing experiment is related by that elegant and ingenious philosopher, the present bishop of Landaff, which is illustrative of the nature of boiling in general, and particularly of what has been just advanced. With an intention of exhibiting a striking instance of the increase of dimensions produced by heat in fluids, he took a glass vessel not unlike the thermometer in form; the bulb contained above a gallon, the stem had a small diameter, and was about two feet in length. This vessel he filled with boiling water to the very top of the stem, and corked it close with a common cork. The water and the cork were at first contiguous, but as the water cooled it contracted, and sunk visibly in the stem; and thus the first intention of the experiment was answered. But here an unexpected phenomenon presented itself. The water, though it was removed from the fire, though it was growing cold, and had for some time entirely ceased from boiling, began to boil very violently. When a hot iron was applied to that part of the stem, through which the water in contracting itself had descended, the ebullition presently ceased: it was renewed when the iron was removed; and it became more than ordinarily violent, when, by the application of a cloth dipped in cold water, that part was cooled. To account for these appearances, it is only necessary to recollect, that by the sinking of the water in the stem, a kind of vacuum is left between its surface and the cork; the water therefore

necessarily boils with a lower degree of heat than it would under the pressure of the atmosphere. The space between the cork and the water is not however a perfect vacuum: it is occupied either by the vapour of the water, or by a small portion of air, or by both. Heat increases the elasticity both of air and vapour, and thus augments the pressure upon the surface of the water, hence the ebullition ceases upon the application of the hot iron. Cold, on the contrary, diminishes the elasticity of the air, and condenses vapour; and thus the pressure upon the surface being lessened by the application of a cold cloth, the ebullition of the water became more violent. The heat of the water when it ceased boiling was 130 degrees.

An experiment of another distinguished philosopher affords perhaps a better illustration of the whole theory which has been just advanced. This gentleman placed a quantity of vitriolic ether under the receiver of an air pump, which was so contrived that he was able to let down a thermometer at pleasure without admiting the external air. He no sooner began to extract the air, than the ether was thrown into a violent ebullition, at the same time its temperature sunk surprisingly. When the ether was first put in, its temperature was about 58 degrees, but it became so cold when boiling, that a quantity of water in a vessel contiguous to it was suddenly frozen. The manner in which these phenomena may be explained is this: The weight of the atmosphere being removed, the heat which the ether contained was sufficient to make it boil. The elementary fire which the ether lost in boiling was disposed of in forming a vapour more subtile than the ether itself; which could not, consistently with the principles established, be formed without the absorption of a considerable quantity of the matter of fire. Now as it appears that water and spirit of wine boil in vacuo at 122 degrees below their ordinary boiling point, it is natural that ether, which boils in the open air at about the heat of the human blood, should boil in vacuo at 24 degrees below 0, a degree of cold sufficient to freeze any water that might happen to be in contact with the vessel which contains the ether.

Every particular liquid has a fixed point at which boiling commences, and this is called the boiling point of the liquid. Thus water begins to boil when heated to 212 degrees. After a liquid has begun to boil, it never becomes hotter, however strong the fire may be to which it is exposed. A strong heat, indeed, makes it boil more rapidly, but does not increase its temperature. This fact was first observed by Dr. Hooke. The following table shows the boiling point of a number of liquids:

Bodies.	*Boiling point.*
Ether	98
Ammonia	140
Alcohol	176
Water	212
Muriat of lime	230
Nitric acid	248
Sulphuric acid	590
Phosphorus	554
Oil of turpentine	560
Sulphur	570
Linseed oil	600
Mercury	660.

The boiling point however is found to depend on the degree of pressure to which the liquid is exposed. If the pressure is diminished, the liquid boils at a lower temperature; if it is increased, a higher temperature is necessary to produce ebullition. From the experiments of professor Robison, it appears that, in a vacuum, all liquids boil about 145 degrees lower than in open air, under a pressure of 30 inches of mercury: therefore water would boil in vacuo at 67 degrees, and alcohol at 34 degrees. In Papin's digester, the temperature of water may be raised to 300 degrees, or even 400 degrees without ebullition; but the instant that this great pressure is removed, the boiling commences with prodigious violence.

BOLE, in mineralogy. This mineral occurs chiefly in the isle of Lemnos, at Sienna in Italy, and in Silesia. Its colour is generally an obscure Isabella yellow, or reddish or whitish brown: it is sometimes, though rarely, met with of a grayish yellow, or flesh red; its surface is often marked with black spots, and dendritic figures. It generally occurs massive; its texture is earthy; fracture conchoidal. Internally it exhibits a slight glimmering lustre, and acquires a polish by friction. When broken with a hammer it flies into irregular sharp edged fragments. The dark coloured varieties are opaque, the lighter coloured are more or less translucid. It has a greasy feel, adheres strongly to the tongue, gives a shining streak, is very soft, and is easily frangible. Specific gravity 1.4 to 2.0.

When put into water it absorbs a little with great eagerness, and breaks down into small fragments with a crackling noise. When finely pulverized, and diffused through boiling water, it remains suspended a less time than any of the plastic clays, and is entirely separable by the filtre. Before the blow pipe it turns black and melts, without any addition, into a porous, greenish, gray flag. The Lemnian bole, according to Bergmann, contains

47.0	Silica
19.0	Alumina
6.0	Carbonate of magnesia
5.4	Carbonate of lime
5.4	Oxide of iron
17.0	Water and air
99.8	

The only use of the bole at present is as a coarse red ingredient; for which purpose it is calcined and levigated, and is sold in Germany under the name of Berlin or English red.

BOLETUS, in botany, spunk; a genus of the order of fungi, belonging to the cryptogamia class of plants. Botanists enumerate 170 species, of which the following are the most remarkable.

1. Boletus bovinus, or cow spunk, is frequent in woods and pastures. It is generally of a brown colour, though sometimes it is tawny, yellowish brown, reddish brown, deep red, purple, or greenish brown. The flesh is yellow, white, or reddish. The young plants are eaten in Italy, and esteemed a great delicacy. The Germans also account them a dainty, calling them *gombas*, and *brat-bulz*. Cows, deer, sheep, and swine, will feed upon this and other boleti, but are sometimes greatly disordered by them. In

cows and other cattle they have been known to create bloody urine, nauseous milk, swellings of the abdomen, inflammations of the bowels, stoppages, diarrhœas, and death. In sheep they are said to bring on a schirrhous liver, a cough, a general wasting, and dropsy. *Scarabs*, *dermestes*, and many other insects, feed upon and breed in them abundantly.

2. Boletus igniarius, or touchwood spunk, is frequent on the trunks of old trees of all kinds, especially ash. It consists of a very hard woody substance, in shape like a horse's hoof; and grows of various sizes, from a man's fist to that of his head and larger. The upper side is smooth, but uneven, distinguished near the rim by elevated zones of different colours, brown, gray, tawny, &c. The flesh is of a tawny brown colour, extremely hard and tough. This fungus is made use of in Germany and some parts of England for tinder. The Germans boil it in strong lye, dry it, and boil it again in solution of saltpetre. The Laplanders burn it about their habitations, in order to keep off a species of the gadfly, which is fatal to the young reindeer. It has been used to stop the bleeding of the vessels after amputations. Phil. Trans. vol. xlviii. p. 2. For this purpose the hard outer part is cut off, and the soft inner substance is beaten with a hammer to make it still softer. It is best when gathered in August or September.

3. Boletus pini laricis, or agaric of the shops, grows on old larch trees. This fungus is an irregular spongy substance, extremely light, and of an uniform snowy whiteness; except the cortical part, which is usually taken off before the agaric is brought into the shops.

4. Boletus suberosus, or white cork spunk, grows commonly on the trunks of birch and willow trees. It grows sessile and horizontal; its figure is semicircular; the upper side convex, the under nearly plain; of various sizes, from that of an ass's hoof to a peck measure. The upper surface is quite white, generally covered with a short strong down, but sometimes smooth. The internal substance is thick, white, tough, light, and spongy, like cork; and is sometimes cut and shaped by the country people in Scotland for corks.

BOLLITO, a name by which the Italians call a sea green colour in artificial crystal. To prepare this colour, you must have in the furnace a pot filled with forty pounds of good crystal, first carefully skimmed, boiled, and purified, without any manganese; then you must have twelve ounces of the powder of small leaves of copper, thrice calcined, half an ounce of zaffer in powder; mix them together, and put them at four times into the pot, that they may the better mix with the glass; stirring them well each time of putting in the powder, for fear that it should swell too much and run over.

BOLLOS, in the mines of Peru, a denomination given to the ingots or bars of silver procured there from the ore, by the operation of fire, and the use of aquafortis.

BOLONIAN *stone*, is a kind of mineral found near Bologna; which, when duly prepared by calcination, makes a species of phosphorus. The property of this stone is, that though it has no lucid appearance in the dark, until it undergoes a particular calcination, it becomes capable by previous preparation, of imbibing, when exposed for a few minutes to the light of day, or even the flame of a candle, such a quantity of light, that it afterward shines in the dark for several minutes, like a glowing coal, but without any sensible heat.

BOLSTERS, in sea language, small cushions, or bags, filled with tarred canvas or rope yarn, &c. and placed under the shrouds and stays, to prevent their chafing against the trestletrees, by the motion of the mast, when the ship rocks at sea.

BOLT, among builders, an iron fastening fixed to doors and windows. They are generally distinguished into three kinds, *viz.* plate, round, and spring bolts.

Bolts, in gunnery, are of several sorts. See Gunnery.

Bolts, in a ship, are iron pins, of which there are several sorts, according to their different make and uses. Such are drive bolts, used to drive out others: ray bolts, with jags or barbs on each side, to keep them from flying out of their holes: clench bolts, which are clenched with riveting hammers: forelock bolts, which have at the end a forelock of iron driven in to keep them from starting back: set bolts, used for forcing the planks, and bringing them close together: fend, or fender bolts, made with long and thick heads, and struck into the uttermost bends of the ship, to save her sides from bruises: and ring bolts, used for brinking to the planks, and those parts whereto are fastened the breeches and tackles of the guns.

Bolt *of canvas*, in commerce, the quantity of 28 ells.

BOLTONIA, in botany, a genus of the class syngenesia, order superflua. The essential characters are, cal. imbricated, cor. radiated, white. There are 3 species all persisting. 1 B. asteroides, starwort flowered Boltonia, flourishes in July, a native of Pennsylvania. 2. B. gloslifolia, a native of Carolina and Pennsylvania. 3. B. affinis, grows in Missouri. (*a.*)

BOMB, in military affairs, a globe or shell of cast iron, having a vent to receive the fuse, which is made of wood, The shell being filled with gunpowder, the fuse is driven into the vent or aperture, within an inch of the head, and fastened with a cement made of quicklime, ashes, brick dust, and steel filings, worked together in a glutinous water; or of four parts of pitch, two of colophony, one of turpentine, and one of wax. This tube is filled with a combustible matter, made of two ounces of nitre, one of sulphur, and three of gunpowder dust, well rammed. To preserve the fuse, they pitch it over, but uncase it when they put the bomb into the mortar, and cover it with gunpowder dust; which having taken fire by the flash of the powder in the chamber of the mortar, burns all the time the bomb is in the air; and the composition in the fuse being spent, it fires the powder in the bomb, which bursts with great force, blowing up whatever is about it. The great height the bomb goes in the air, and the force with which it falls, make it go deep into the earth.

Bomb *chest*, a kind of chest filled usually with bombs, sometimes only with gunpowder, placed under ground to tear it and blow it up into the air, with those who stand on it. It was set on fire by means of a saucisse fastened at one end, but is now much disused.

BOMBARDMENT, the act of assaulting a city or fortress, by throwing shells into it, in order to set fire to and ruin the houses, churches, magazines, &c. and to do other mischief. As one of the effects of the shell results from its weight, it is never discharged as a ball from a cannon, that is, by pointing it point blank at a certain object;

but the mortars in England are fixed at an elevation of 45 degrees; that is, inclined so many degrees from the horizon, that the shell describes a curve, called the military projectile. Hence a mortar, whose trunnions are placed at the breech, can have no point blank range. Mortars should be so contrived, that they may be elevated to any degree required, as much preferable to those fixed at an angle of 45°; because shells should never be thrown at that angle but in one single case only, which seldom happens; that is, when the battery is so far off, that they cannot otherwise reach the works: for when shells are thrown from the trenches into the works of a fortification, or from the town into the trenches, they should have as little elevation as possible, in order to roll along, and not bury themselves; whereby the damage they do, and the error they cause to the troops, is much greater than if they sink into the ground. On the contrary, when shells are thrown upon magazines, or any other buildings, with an intention to destroy them, the mortar should be elevated as high as possible, that the shells may acquire a greater force in their fall.

Shells should be loaded with no more powder than is requisite to burst them into the greatest number of pieces, and the length of the fuses should be exactly calculated according to the required ranges; for, should the fuse set fire to the powder in the shell before it falls on the place intended, the shell will burst in the air, and probably do more mischief to those who fired the mortar than to those against whom it was discharged. To prevent this, the fuses are divided into as many seconds as the greatest range requires, consequently may be cut to any distance, at an elevation of 45 degrees.

Mortars are not to be fired with two fires; for when the fuse is properly fixed, and both fuse and shell dredged with mealed powder, the blast of the powder in the chamber of the mortar, when inflamed by the tube, will likewise set fire to the fuse in the shell.

BOMBASINE, a name given to two sorts of stuffs, the one of silk, and the other crossed of cotton.

Bombasine of silk pays duty on importation as other foreign silks. See Silk. That of cotton pays each piece, a duty according to its width.

BOMBAX, in botany, the silk cotton tree: a genus of the polyandria order, and monodelphia class of plants; and in the natural method ranking under the 37th order, columniferæ. The calyx is quinquifid; the stamina are five or more; the capsule is ligneous, quinquelocular, and quinquevalved; the seeds are woolly, and the receptacle pentagonous. The species are:

1. Bombax ceiba, with a prickly stalk.

2. Bombax heptaphyllum, with leaves cut into seven parts. The cotton is of a fine purple colour, but the size of the tree is not particularly mentioned by botanical writers.

3. Bombax pentandrum, with a smooth stalk. This and the ceiba grow naturally in both the Indies, where they arrive at a great magnitude, being some of the largest trees in these parts. Bosman says, he has seen in Guinea trees of this kind so widely diffused, that 20,000 armed men might stand under the branches of one. They generally grow with straight stems. Those of the ceiba are armed with short strong spines; but the pentandrum has a very smooth stem, which in the young plant is of a bright green; but after a few years is covered with a gray or ash coloured bark, which turns brown as they grow older. The branches toward the top are furnished with leaves composed of five, seven, or nine, oblong smooth little leaves, spear shaped, and joined to one common centre at their base, where they adhere to the long footstalk. The flower buds appear at the end of the branches; and soon after the flowers expand, which are composed of five oblong purple petals, with a great number of stamina in the centre; when these fall off, they are succeeded by oval fruit as large as a swan's egg, having a thick ligneous cover, which, when ripe, opens in five parts, and is full of a dark short cotton, enclosing many roundish seeds as large as small peas.

4. Bombax gossipinum. Besides the species above described, Mr. Miller mentions another which he saw in the gardens of the late duke of Richmond at Goodwood, and was raised from seeds which came from the East Indies.

These plants, being natives of warm climates, must always be kept in a stove. They are raised from seeds procured in the capsules from the places where they grow naturally. They must be watered plentifully in summer, but moderately in winter.

The dark short cotton of the first and third species is used by the poorer inhabitants of those places where such trees grow, to stuff pillows or chairs, but is generally deemed unwholesome to lie upon. The beautiful purple down of the heptaphyllum is spun, wrought into clothes, and worn without being dyed any other colour, by the inhabitants of the Spanish West Indies, where the tree naturally grows. Large pirogues, or canoes fit to carry a sail, are made both at Senegal and in America, of the trunk of the silk cotton tree, the wood of which is very light, and unfit for any other purpose. In Columbus's first voyage, it was reported that a canoe was seen at Cuba made of the hollowed trunk of one of these trees, capable of containing 150 men.

BOMB KETCH. The modern bomb vessels carry two ten inch mortars, four 68 pounders, and six 18 pounders, carronades; and the mortars may be fired at as low an angle as 20 degrees; their principal use being to cover the landing of troops, and to protect our coasts and harbours. A bomb ketch is from 60 to 70 feet long, and draws eight or nine feet water.

BOMBIC *acid*. The silkworm has a small reservoir near the anus, from which, when full grown, or especially when it is in the chrysalis state, a minute quantity of acid liquor is seen to ooze out. If the entire animal is bruised, it gives a liquor containing the usual soft animal matters, with a native acid. Alcohol separates the former, and leaves the latter in solution; which, by evaporation, furnishes a very sour pungent yellow fluid, which exhibits all the marks of an acid, by reddening blue vegetables, and uniting with alkalies.

BOMBYLIUS, in entomology, a genus of dipterous insects distinguished by the following character: beak or sucker very long, setaceous, straight, and consisting of two unequal valves, within which three setaceous bristles are contained; feelers two, short and hairy: antennæ subulate, and connected at the base.

The antennæ are short, and contain three articulations, the first of which is long, the second short, and the third or last conical, and terminating in a kind of appendage, almost forming a fourth joint, as is to be observed with the

assistance of glasses. Those who have carefully examined the structure of the trunk with the microscope affirm, that the number of valves or bristles concealed within the external bivalve sheath are four, instead of three as Gmelin describes them. The antennæ are inserted at the base of the trunk.

Insects of this genus have the head comparatively of a small size, of a form somewhat rotund, and almost wholly occupied by the eyes. The thorax large, the abdomen bulky and rounded at the extremity, as in the bee. Both the thorax and abdomen are hairy, or covered with down. The wings longer than the body, and extended horizontally. Legs long and slender. The size and rotundity of the body afford an excellent natural character, by which this tribe of insects may be distinguished from those of the genera empis and asilus, with which some naturalists have confounded them. The Fabrician species of volucella, cytherea, and anthrax, have been referred to the bombylius genus with very little propriety. The true bombylius is a lively active tribe of insects, that subsist entirely on the nectareous juices they extract from flowers, with the assistance of their long proboscis or trunk. They fly with much rapidity, making all the time a soft humming noise similar to that of the bee. In England the largest species, major, has acquired the name of the humblebee fly. The insects of this tribe are found in the winged state in the summer, but their metamorphose is utterly unknown. Only a small number of species in this genus are at present known. See Plate XV. Nat. Hist. fig. 52, and 53.

BOMBYX, a genus of lepidopterous insects, or rather one of the subdivisions of the phalæna, an extensive genus, in which all the insects of the moth tribe are comprised by Linnæus. Fabricius, in his "Entomologia systematica," admits the bombyx as a genus, applying the term phalæna, which Linnæus gave indiscriminately to all the species of the moth tribe, as a generical name to that particular description of moths which have the palpi cylindrical, the tongue advanced and membranaceous, and the antennæ filiform. In the Systema Naturæ, Linnæus divides the bombyces into sections in the following order: the elingues, or those without a manifest spiral tongue; and the spirilingues, having an involuted tongue. These two principal sections are subdivided again; the elingues, into those with the back smooth or not crested, with expanded wings, with reversed wings, with deflected wings, with erect crests or tufts on the backs; and the spirilingues, those smooth, with expanded wings, and with deflected wings, and with the back crested.

The insects of the bombyx tribe never fly except in the evening. During the day time they secrete themselves under the leaves, or beneath the branches, in the clefts of trees, where they may remain secure till about sunset, at which time they appear to be on the alert; at first crawling about the branches, then fluttering their wings, and becoming brisker in all their motions as the evening advances. The larger sort of moths, which we see first starting from the woods or hedges after some of the geometræ, are the swifts, the Fabrician hepiali; which fly swiftly, as their trivial name implies, but low or near the surface of the ground: these at twilight are succeeded by the bombyces and noctuæ, whose flight is more elevated. They continue to sport about till it becomes quite dark. The males of the bombyces are commonly first upon the wing in search of the females; which latter are, in some few species, entirely destitute of wings, or at least have only the rudiments of them close to the thorax; in which case the female waits upon the trees or herbage for the arrival of the male: the female of bombyx antiqua, the vapourer moth, is a striking proof of this; for it has so little the appearance of a moth that any one, except an entomologist, would mistake it for an apterous or wingless insect. Those females which have wings are commonly larger even than the males.

The bombyces are produced from a larva, or as it is more usually termed by common observers, a caterpillar. This is of a long cylindrical form, having in some species a smooth skin, or in others more or less tuberculated; sometimes the skin is covered with a fine silky down, or with hairs; and some of the larger kinds are armed with spines and bristles. All the larvæ of the bombyces subsist on vegetables. Their jaws are strong, and of a horny texture; and below them is a small opening, through which the creature draws the silky thread of so much utility in its general economy. Most of these larvæ have 16 feet, some have only 14 feet, and others no more than 12; six of which are hooked, and situated on the three first annulations near the head, the others toward the lower extremity of the body are short, broad, and very different in structure.

The greater number of species in the bombyx tribe, when in the larva state, lead a solitary life; in which case they separate as soon as they are hatched from the eggs, and crawl about to provide for themselves, the smallest of these even being able to obtain its own subsistence; they can eat as readily, and spin, or throw out the silky thread with as much facility, as when grown bigger. The latter is of considerable utility to the larva; for when it wishes to descend from one branch of the tree or bush to another, instead of being obliged to pursue a circuitous course, by crawling or walking, it need only fasten one end of the silken thread to any particular spot, and lower itself by its assistance to the branch desired; or when suspended midway between the branches, it can pass aside with a swing to any other point within a convenient distance. In like manner, when observed by birds or other enemies, it can drop in an instant, and elude the enemy; waiting concealed below among the leaves or on the ground till the danger is over, and then remounting to the former spot by the aid of this thread. This is a provision of nature for the security of the larvæ of the bombyces, in common with that of other lepidopterous insects.

Some species of the bombyces live in societies, as may be observed, for instance, in bombyx neustria of entomologists, the lack eye moth of English collectors. The larvæ of this species, by their united labours, spin a capacious habitation, in which the infant brood is hatched from the egg, and after undergoing their several transformations, finally become moths.

Like other larvæ of the moth tribe, those of the bombyces cast their skin several times. When full grown, and approaching the pupa state, those of the bombyx kind spin a sort of web, in which we find the most valuable silk produced by these creatures at any time of their lives. The silk spun by the hairy larvæ is observed to be of little value, because the creature interweaves it with the hairs it plucks off its skin for this purpose. The common silkworm, bombyx mori, whose cocoon consists of the most

valuable kind of silk, as is well known, has the skin perfectly smooth, or free from hair. There are certain species of the larger bombyces, the larvæ of which have smooth skins, but still beset with annular series of spines or bristles, that produce very strong silk, and are reared with the view of obtaining the cocoons for the manufacture of silk in the East Indies. The breed of these useful insects has long been cultivated in India, although the silk produced from them is very little, if at all, known in Europe. The bombyces remain in the pupa state for a certain time, varying according to the species, some only a few days or weeks, others six or twelve months, two years, or even three. The same day that the creatures emerge from the pupa state they are in a condition to perpetuate their race. Almost immediately after coupling, the males die; the females live long enough to deposite the eggs in a proper place for their security, and where the infant brood may find subsistence, after which they perish likewise.

The species of the bombyx tribe are numerous. Those already described by naturalists amount to a large number; and there are, in the cabinets of the curious, many more, especially of the extra European species, that have never been described; even in the collections of this country, those of the latter description are numerous.

BONA NOTABILIA, are such goods as a person dying has in another diocese than that wherein he dies, amounting to the value of 5*l.* at least; in which case the will of the deceased must be proved, or administration granted, in the court of the archbishop of the province, unless by composition or custom any dioceses are authorized to do it, when rated at a greater sum.

BOND. A bond, or obligation, is a deed whereby the obligor, or person bound, binds himself, his heirs, executors, and administrators, to pay a certain sum of money, or do some other act; and there is generally a condition added, that if he do perform such act, the obligation shall be void, or else remain in full force; as performance of covenants, standing to an award, payment of rent, or repayment of a principal sum of money with interest, which principal sum is usually half the sum specified in the bond. 2. Blacks. 340.

All persons who are enabled to contract, and whom the law supposes to have sufficient freedom and understanding for that purpose, may bind themselves in bonds and obligations. 1 Rol. Abr. 340.

If the condition of a bond is impossible at the time of making it, if it is to do a thing contrary to some rule of law, or to do a thing that is malum in se, the obligation itself is void. The bond of a feme covert is void, as is that of an infant. If a person is illegally restrained of his liberty, and during such restraint enters into a bond to a person who causes the restraint, the same may be avoided for duress of imprisonment. 2 Inst. 482.

To avoid controversies, three things are necessary to making a good obligation, signing, sealing, and delivery. A bond, on which neither principal nor interest has been demanded for 20 years, will be presumed in equity to be satisfied. If several obligors are bound jointly and severally, and the obligee makes one of them his executor, it is a release of the debt, and the executor cannot sue the other obligor. 8 Cor. 136.

If one obligor makes the executor of an obligee his executor, and leaves assets, the debt is deemed satisfied; for he has power by way of retainer to satisfy the debt. A release to one obligor is a release to all, both in law and equity. 1 Atk. 294.

BOND, *post obit*, one and the main condition of which is, that it only becomes payable after the death of some person, whose name is therein specified. The death of any person being uncertain as to time, the risk attached to such bonds frees them from the shackles of the common law of usury. It has been determined, that bonds bought for half their value did not amount to usury, on account of the risk with which they were attended.

BOND, in carpentry, a term among workmen; as, to make good bond, means that they should fasten the two or more pieces together either by tenanting, mortising, or dovetailing, &c.

BOND, in masonry and bricklaying, is when bricks or stones are so interwoven that the joints are not made over or upon other joints, but reach at least six inches both within the wall and on the surface, as the art of building requires.

BONDAGE *by firelock*, was when a freeman renounced his liberty, and became slave to some great man: which was done by the ceremony of cutting off a lock of hair on the forehead, and delivering it to his lord; denoting that he was to be maintained for the future. Such bondman, if he reclaimed his liberty, or was fugitive from his master, might be drawn again to his servitude by the nose: hence is said to be the origin of the popular menace to pull a man by the nose.

BONE, in chymistry and the arts. The bones are the most solid part of animals. Their texture is sometimes dense, at other times cellular and porous, according to the situation of the bone. They are white, of a lamellar structure, and not flexible nor softened by heat. Their specific gravity differs in different parts. That of adults' teeth is 2.2727: the specific gravity of children's teeth is 2.0833. It must have been always known that bones are combustible, and that when sufficiently burnt they leave behind them a white porous substance, which is tasteless, absorbs water, and has the form of the original bone. The nature of this substance embarrassed the earlier chymist. In 1771, Scheele mentioned in his dissertation on fluor spar, that the earthy part of bones is phosphat of lime. This discovery was the first and the great step toward a chymical knowledge of the composition of bones. Afterward, some new facts were made known by Berniard, Bouillon, and Rouelle; but for by far the most complete analysis that has hitherto appeared we are indebted to Mr. Hatchett.

The component parts of bones are chiefly four: namely, the earthy salts, fat, gelatine, and cartilage.

1. The earthy salts may be obtained either by calcining the bone to whiteness, or by steeping it for a sufficient length of time in the acids. In the first case, the salts remain in the state of a brittle white substance. In the second, they are dissolved, and may be thrown down by the proper precipitants. These earthy salts are three in number: 1. Phosphat of lime, which constitutes by far the greatest part of the whole. 2. Carbonate of lime. 3. Sulphat of lime, which forms the smallest part. To estimate these substances, calcined bones, or the raspings of bones, may be dissolved in nitric or muriatic acid. During the solution carbonic acid gas makes its escape. Pure ammonia dropped into the solution throws down the phosphat of lime in the state of a fine powder, readily sol-

uble without effervescence by nitric, muriatic, and acetic acids. Nitrat of barytes afterward causes a small precipitate insoluble in muriatic acid, and therefore consisting of sulphat of barytes. Its weight indicates the quantity of sulphuric acid in bones, from which the sulphat of lime which they contain may be estimated. Carbonate of ammonia now throws down pure carbonate of lime. These three constituents were found by Hatchett in all the bones of quadrupeds and fish which he examined. The carbonate scarcely exceeds the fifth part of the phosphat, and the proportion of sulphat is still smaller.

2. The proportion of fat contained in bones is no less various. By breaking bones in small pieces, and boiling them for some time in water, Mr. Proust obtained their fat swimming on the surface of the liquid. It weighed, he says, one fourth of the weight of the bones employed. This proportion appears excessive, and can scarcely be accounted for without supposing that the fat still retained water.

3. The gelatine is separated by the same means as the fat, by breaking the bones in pieces, and boiling them long enough in water. The water dissolves the gelatine, and gelatinizes when sufficiently concentrated. Hence the importance of bones in making portable soups, the basis of which is concrete gelatine, and likewise in making glue. By this process Proust obtained from powdered bones about 1-16th of their weight in gelatine.

4. When bones are deprived of their gelatine by boiling them in water, and of their earthy salts by steeping them in diluted acids, there remains a soft white elastic substance, possessing the figure of the bones, and known by the name of cartilage. From the experiments of Mr. Hatchett, it appears that this substance has the properties of coagulated albumen. Like that substance, it becomes brittle and semitransparent when dried, is readily soluble in hot nitric acid, is converted into gelatine by the action of diluted nitric acid; for it is soluble in hot water, and gelatinizes on cooling, and ammonia dissolves it and assumes a deep orange colour. Like coagulated albumen, it forms an animal soap with fixed alkalies.

This cartilaginous substance is the portion of the bone first formed. Hence the softness of these parts at first. The phosphat of lime is afterward gradually deposited, and gives the bone the requisite firmness. The gelatine and fat, especially the first, gave the bone the requisite degree of toughness and strength; for when they are removed, the bone becomes brittle. The relative proportion of phosphat of lime and cartilage differs exceedingly in different bones and in different animals.

One hundred parts contain	Gelatine	Phos. of lime.	Car. of lime.	Loss.

Bones, diseases of, see Surgery.

Bones, fossil or petrified, are those found in the earth, frequently at great depths in all strata, even in the bodies of stones and rocks. Some of these bones are of a huge size, usually supposed to be the bones of giants, but more truly of elephants or hippopotami, others smaller, as the vertebræ, teeth, and the like. It has indeed been disputed whether these are really animal substances or mineral; but a chymical investigation proves them to be animal; and they were probably deposited in those strata at a time when all things were in a state of solution, and they incorporated and petrified with the bodies where they happened to be lodged.

Mr Hatchett examined some fossil bones from the rock of Gibralter. He found them to consist of phosphat of lime without any cartilage or soft animal part. Their interstices were filled with carbonate of lime. Hence they resemble exactly bones that have been burnt. They must then have been acted on by some foreign agent; for putrefaction, or lying in the earth, does not soon destroy the cartilaginous part of bones. On putting a human os humeri, brought from Hythe in Kent, and said to have been taken from a Saxon tomb, into muriatic acid, he found the cartilaginous residuum nearly as complete as in a recent bone.

Bone-*ace*, properly *bon*, or good, *ace*, an easy game at cards, played thus: The dealer deals out two cards to the first hand, and turns up the third, and so on through all the players, who may be seven, eight, or as many as the cards will permit; he that has the highest card turned up to him carries the bone, that is, one half of the stake, the other remaining to be played for. Again, if there are three kings, three queens, three tens, &c. turned up, the eldest hand wins the bone; but it is to be observed, that the ace of diamonds is bon-ace, and wins all other cards whatever. Thus much for the bone; and as for the other half of the stake, the nearest to 31 wins it, and he that turns up or draws 31 wins it immediately.

BONING, in surveying and levelling, is the placing of three or more rods or poles, all of the same length, in or upon the ground in such a manner that their tops may be all in one continued straight line, whether it is horizontal or inclined, so that the eye may look along the tops of them all, from one end of the line to the other.

BONNET, in fortification, a small work, consisting of two faces, having only a parapet with two rows of palisadoes, of about ten or twelve feet distance. It is generally raised before the salient angle of the counterscarp, and has a communication with the covered way by a trench cut through the glacis, and palisadoes on each side.

Bonnet *à prelre*, or priest's bonnet, in fortification, is an outwork, having at the head three salient angles, and two inward. It differs from the double tenaille only in this; that its sides, instead of being parallel, are like the *queue d'aronde*, or swallow's tail, that is, narrowing or drawing close at the gorge, and opening at the head.

Bonnet, in the sea language, denotes an addition to a sail; thus they say, lace on the bonnet, or shake off the bonnet.

BONPLANDIA gemini flora, in botany, a plant of the class pentandria, order monogynia, cal. liber tubulous 5 toothed, cor. 5 parted, stam. declinate, stig. trifid, cap. ovato trigona, 3 celled, 3 sperm. stem elliptical. (*b.*)

BONTIA, wild olive of Barbadoes, a genus of the angiospermia order and didynamia class of plants, and in the natural method ranking under the 40th order, perso-

natæ. The calyx is quinquepartite; the corolla is bilabiated, the inferior lip tripartite and revolute; the drupe is ovate and monospermous, with the apex turned to one side. There is one species, *viz.*

Bontia daphnoides has a woody stem and branches, rising to the height of ten feet, with narrow, smooth, thickish leaves, and flowers from the sides of the branches, succeeded by large oval fruit that sometimes ripens in England. This species is generally cultivated in the gardens at Barbadoes for hedges; for which it is exceedingly proper, being an evergreen of very quick growth. It is said that from cuttings planted there in the rainy season, when they have immediately taken root, there has been a complete hedge four or five feet high in 18 months.

BONZES, Indian priests, who, in order to distinguish themselves from the laity, wear a chaplet round their heads, consisting of an hundred beads, and carry a staff, at the end of which is a wooden bird. They live upon the alms of the people, and yet are very charitably disposed, maintaining several orphans and widows out of their own collections.

BOOK *binding*, the art of gathering and sewing together the sheets of a book, and covering it with a back, &c. It is performed thus: the leaves are first folded with a folding stick, and laid over each other in the order of the signatures, which are the letters with the numbers annexed to them at the bottom of the pages of the first one, two, or more leaves in each sheet. The leaves thus folded are then beaten on a stone with a hammer, to make them smooth and open well, and afterward pressed. While in the press they are sewed upon bands, which are pieces of cord or packthread; six bands to a folio book, five to a quarto, octavo, &c. which is done by drawing a thread through the middle of each sheet, and giving it a turn round each band, beginning with the first and proceeding to the last. After this the books are glued, and the bands opened and scraped, for the better fixing the pasteboards; the back is turned with a hammer, and the book fixed in a press between two boards, in order to make a groove for fixing the pasteboards; these being applied, holes are made for fixing them to the book, which is pressed a third time. Then the book is at last put to the cutting press, betwixt two boards, the one lying even with the press for the knife to run upon, the other above it for the knife to run against: after which the pasteboards are squared.

The next operation is the sprinkling the leaves of the book, which is done by dipping a brush into vermilion and sap green, holding the brush in one hand, and spreading the hair with the other; by which motion the edges of the leaves are sprinkled in a regular manner, without any spots being larger than the other.

The covers, which are either of calf or of sheep skin, being moistened in water, are next cut out to the size of the book, then smeared over with paste made of wheat flour, and afterward stretched over the pasteboard on the outside, and doubled over the edges withinside, after having first taken off the four angles, and indented and platted the cover at the head band; which done, the book is covered and bound firmly between two hands, and then set to dry. Afterward it is washed over with a little paste and water, and then sprinkled fine with a brush; unless it should be marbled, when the spots are to be made larger by mixing the ink with vitriol. After this the book is glazed twice with the white of an egg beaten, and at last polished with a polishing iron passed hot over the glazed cover.

The letters or other ornaments on books are made with gilding tools engraved in relievo, either on the points of punchers, or around little cylinders of brass. The punchers make their impressions by being pressed flat down, and the cylinders by being rolled along by a handle, to which they are fitted on an iron axis. To apply the gold, the binders glaze the parts of the leather with a liquor made of whites of eggs diluted with water, by means of a piece of sponge; and when nearly dry, the pieces of gold leaf are laid on, and the tools being made hot in a charcoal fire, are applied.

Book *keeping*, an art teaching how to record and dispose the accounts of business, so that the true state of every part and of the whole may be easily and distinctly known.

Merchants' books are kept either single, or according to the method of double entry. Those who keep them in the former method have occasion for few books, as a journal or day book, and a ledger or post book; the former to write all the articles, following each other as they occur in the course of their business, and the other to draw out the accounts of all the debtors and creditors on the journal. This method is only proper for retail dealers, or at least for traders who have but very little business; but as for wholesale dealers and great merchants, who keep their books according to the double entry, or Italian method, as is now most commonly done, their business requires several other books, the usefulness of which will be seen from what follows.

The most considerable books, according to the method of double entry, are the waste book, the journal, and the ledger; but besides these three, which are absolutely necessary, there are several others, to the number of thirteen, or even more, called subservient or auxiliary books, which are used in proportion to the business a man has, or to the nature of the business that he carries on. These books are the cash book, the debt book, the book of numeros, the book of invoices, the book of accounts current, the book of commissions, orders, or advices, &c.

The waste book may be defined a register, containing an inventory of a merchant's effects and debts, with a distinct record of all his transactions and dealings, in a way of trade, related in a plain simple style, and in order of time as they succeed one another.

The waste book opens with the inventory, which consists of two parts; first, the effects, that is, the money a merchant has by him, the goods he has in hand, his part of ships, houses, farms, &c. with the debts due to him; the second part of the inventory is the debts due by him to others; the difference between which and the effects is what the merchants call neat stock. When a man begins the world, and first sets up to trade, the inventory is to be gathered from a survey of the particulars that make up his real estate; but ever after it is to be collected from the balance of his old books, and carried to the new.

After the inventory is fairly related in the waste book, the transactions of trade come next to be entered down, which is a daily task, to be performed as they occur. The narrative ought to exhibit transactions with all the circumstances necessary to be known, and no more. It

should contain the names of persons with whom the merchant deals upon trust, the conditions of bargains, the terms of payment, the quantity, quality, and prices of goods, with every thing that serves to make the record distinct, and nothing else. The waste book, if no subsidiary books are kept, should contain a record of all the merchant's transactions and dealings in the way of trade; and that not only of such as are properly and purely mercantile, but of every occurrence that affects his stock, so as to impair or increase it, such as private expenses, servants' fees, house rents, money gained, &c.

The journal is the book in which the transactions recorded in the waste book are prepared to be carried to the ledger, by having their proper debtors and creditors ascertained and pointed out: whence it may be observed that the great design of the journal is to prevent errors in the ledger: again, after the ledger is filled up, the journal facilitates the work required in revising and correcting it; for first the waste book and journal are compared, and then the journal and ledger; whereas to revise the ledger immediately from the waste book would be a matter of no less difficulty than to form it without the help of a journal: lastly, the journal is designed as a fair record of a merchant's business, for neither of the other two books can serve this purpose; not the ledger, by reason of the order that obtains in it, and also on account of its brevity, being little more than a large index: nor can the waste book answer this design, as it can neither be fair nor uniform, nor very accurate, being commonly written by different hands, and in time of business. Hence it is that in case of differences between a merchant and his dealers, the journal is the book commonly called for and inspected by a civil judge.

In the journal, persons and things are charged debtors to other persons and things as creditors; and in this it agrees with the ledger, where the same style is used, but differs from it as to forms and order; so that it agrees with the waste book in those very things where it differs from the ledger; and, on the other hand, it agrees with the latter, in the very point wherein it differs from the former; but in order to state the comparison betwixt the waste book and journal, we shall turn two or three examples of the waste book into a journal form.

WASTE BOOK.

July 1st.				*l.*	*s.*	*d.*
Bought of William Pope 40 yards of black cloth at 14*s.* per yard, payable in three months - - - - - - - -				28	00	00

It may be here observed, that every case or example of the waste book, when entered into the journal, is called a journal post or entrance; thus the examples above make three direct posts. Again, a post is either simple or complex: a simple post is that which has but one debtor, and one creditor, as the first of these above; a complex post is either when one debtor is balanced by one or more creditors, as in the second post or when two or more debtors are balanced by one creditor, as in the third post; or when several debtors are balanced by several creditors, and then the post is said to be complex in both terms. This being premised, the following rules are to be observed for writing in the journal.

1. In a simple post, the debtor is to be expressly mentioned, then the creditor, and lastly the sum, all in one line; after which the narrative or reason of the entry, in

one or more lines, as in the first of these three posts above.

2. In a complex post, the several debtors or creditors are expressed in the first line by themselves, with their respective sums subjoined to them; which are to be added up, and their total carried to the money columns, as in the second and third posts

3. The debtors and creditors should be written in a large letter or text hand, both for ornament and distinction.

Before we proceed to explain the ledger, we shall previously inquire into the nature and use of the terms debtor and creditor, as the whole art of book keeping entirely depends on a true idea of those terms, the nature and use of which will be obvious from the following considerations:

Accounts in the ledger consist of two parts, which in their own nature are directly opposed to and the reverse of one another, which are therefore set fronting one another, and on opposite sides of the same folio. Thus all the articles of the money received go to the left side of the cash account; and all the articles or sums laid out are carried to the right. In like manner the purchase of goods is posted to the left side of the accounts of the said goods, and the sale or disposal of them to the right.

Transactions of trade, or cases of the waste book, are also made up of two parts, which belong to different accounts, and to opposite sides of the ledger, *e.g.* If goods are bought for ready money, the two parts are the goods received and the money delivered; the former of which goes to the left side of the account of the said goods, and the latter to the right side of the cash account.

The two parts in any case in the waste book, when posted to the journal, are denominated the one the debtor, the other the creditor of that post; and when carried thence to the ledger, the debtor or debtor part is entered upon the left side, hence called the debtor side, of its own account, where it is charged debtor to the creditor part. Again, the creditor or creditor part is posted to the right side or creditor side of its account, and made creditor by the debtor part. Hence Italian book keeping is said to be a method of keeping accounts by double entry, because every single case of the waste book requires at least two entries in the ledger, *viz.* one for the debtor and another for the creditor.

From what has been said it is evident that the terms debtor and creditor are nothing else but marks or characteristics stamped upon the different parts of transactions in the journal, expressing the relation of these parts to one another, and showing to which side of their respective accounts in the ledger they are to be carried.

Having thus far explained the meaning of the terms debtor and creditor, we shall now proceed to the ledger, or principal book of accounts.

Of the ledger. The ledger is the principal book wherein all the several articles of each particular account that lie scattered in other books, according to their dates, are collected and placed together in spaces allotted for them, in such a manner that the opposite parts of every account are directly set fronting one another, on opposite sides of the same folio.

The ledger's folios are divided into spaces for containing the accounts, on the head of which are written the titles of the accounts, marked Dr. on the left hand page, and Cr. on the right; below which stand the articles, with the word *To* prefixed on the Dr. side, and the word *By* on the Cr. side; and upon the margin are recorded the dates of the articles, in two small columns allotted for that purpose. The money columns are the same as in other books; before them stand the folio column, which contains figures directing to the folio where the corresponding ledger entrance of each article is made; for every thing is twice entered in the ledger, *viz.* on the Dr. side of one account, and again on the Cr. side of some other account; so that the figures mutually refer from the one to the other, and are of use in examining the ledger. Besides these columns, there must be kept in all accounts, where number, measure, weight, or distinction of coins is considered, inner columns to insert the quantity; and for the ready finding any account in the ledger, it has an alphabet or index, wherein are written the titles of all accounts, with the number of the folio where they stand.

How the ledger is filled up from the journal. 1. Turn to the index, and see whether the Dr. of the journal post, to be transported, is written there: if not, insert it under its proper letter, with the number of the folio to which it is to be carried.

2. Having distinguished the Dr. and the Cr. sides, as already directed, recording the dates, complete the entry in one line, by giving a short hint of the nature and terms of the transaction, carrying the sum to the money columns; and inserting the quantity, if it is an account of goods, &c. in the inner columns, and the referring figure in the folio column.

3. Turn next to the creditor of the journal post, and proceed in the same manner with it, both in the index and ledger; with this difference only, that the entry is to be made on the Cr. side, and the word By prefixed to it.

4. The post being thus entered in the ledger, return to the journal, and on the margin mark the folios of the accounts, with the folio of the Dr. above, and the folio of the Cr. below, and a small line between them thus $\frac{1}{2}$. These marginal numbers of the journal, are a kind of index to the ledger, and are of use in examining the books, and on other occasions.

5. In opening the accounts in the ledger, follow the order of the journal; that is, beginning with the first journal post, allow the first space in the ledger for the Dr. of it, the next for the Cr. the third for the Dr. of the following post, if it is not the same with some of those already opened, and so on till the whole journal be transported: and supposing that, through inadvertency, some former space has been allowed too large, you are not to go back to subdivide it, in order to erect another account in its stead.

Though these rules are formed for simple posts, where there is but one Dr. and one Cr. yet they may be easily applied to complex ones.

As an example how articles are to be entered in the ledger, take the two accounts of Cash and William Pope, so far as mentioned in the above waste book and journal.

JOURNAL.

1806.		Cash Dr.	Fo.	l.	s.	d.	1806.		Contra Cr.	Fo.	l.	s.	d.
July	4	To port wine received in part for four pipes, at 27*l.* 10*s.* per pipe.	6	55	00	00	July	1	By shalloon, paid in part for 100 yards at 10*d.* per yard.	12	2	00	00
							July	1					
July	4	Wil. Pope, Dr.							Contra Cr.				
		To port wine, as per journal.	6	55	00	00			By black cloth, for 40 yards, at 14*s.* per yard.	3	28	00	00

Cash book. This is the most important of the auxiliary books. It is so called, because it contains, in debtor and creditor, all the cash that comes in, and goes out of, a merchant's stock; the receipts on the debtor side; the persons of whom it was received, on what, and on whose account, and in what specie: and the payments on the creditor side; mentioning also the specie, the reasons of the payments, to whom, and for what account they are made.

Book of debts or payments, is a book in which is written down the day on which all sums become due, either to be received or paid, by bills of exchange, notes of hand, merchandises bought or sold, or otherwise. By comparing receipts and payments, one may, in time, provide the necessary funds for payments, by getting the bills, notes, &c. due to be paid, or by taking other precautions.

Book of numeros or wares. This book is kept in order to know easily all the merchandises that are lodged in the warehouse, those that are taken out of it, and those that remain therein.

Book of Invoices. This book is kept to perserve the journal from erasures, which are unavoidable in drawing up the accounts of invoices of the several merchandises received, sent out, or sold; wherein one is obliged to enter very minute particulars. It is also designed to render those invoices easier to find than they can be in the waste book or journal.

Book of accounts current. This book serves to draw up the accounts which are to be sent to correspondents, in order to settle them in concert, before they are balanced in the ledger; it is properly a duplicate of the accounts in the ledger which is kept to have recourse to occasionally.

The other mercantile books generally in use are, the book of commissions, orders, or advices; the book of acceptances of bills of exchange; the book of remittances; the book of expenses; the copy book of letters; the book of postage; the ship books; and the book of workmen. To these may be added others, which depend on the greater or lesser accuracy of the merchants and bankers, and on the several kinds of trade carried on by particular dealers.

BOOKS. By 8 Anne, c. 19. the author of any book, and his assigns, shall have the sole liberty of printing and reprinting the same for twenty-one years, to commence from the day of the first publication thereof, and no longer; except that if the author be living at the expiration of the said term, the sole copyright shall return to him for other fourteen years; and if any other person shall print, or import, or shall sell or expose it to sale, he shall forfeit the same, and also one penny for every sheet thereof found in his possession. But this shall not expose any person to the said forfeitures, unless the title thereof shall be entered in the register book of the company of stationers.

By 41 Geo. III. eleven copies of each book, on the best paper, shall, before publication, be delivered to the warehouse keeper of the company of stationers, for the use of the royal library, the libraries of the two universities in England, the four universities in Scotland, the library of Sion college, the library belonging to the college of advocates in Edinburgh, the library of Trinity college Dublin, and the king's inns Dublin, on pain of forfeiting the value thereof, and also 5*l.*

By stat. 34 Geo. III. c. 20. and 41 Geo. III. c. 107, persons importing for sale books first printed within the united kingdom, and reprinted in any other, such books shall be seized and forfeited; and every person so exposing such books to sale, for every such offence shall forfeit the sum of 10*l.* The penalties not to extend to books not having been printed for twenty years.

By the act of union, 40 Geo. III. c. 67. all prohibitions and bounties on the export of articles, the produce and manufacture of either country, to the other shall cease; and a countervailing duty of two pence for every pound weight avoirdupois of books, bound or unbound, and of maps and prints, imported into Great Britain, directly from Ireland, or which shall be imported into Ireland from Great Britain, is substituted.

BOOM, in the sea language, a long piece of timber with which the clew of the studding sail is spread out; and sometimes the boom is used to spread or boom out the clew of the mainmast.

The different kinds of booms have different names according to the purposes for which they are intended.

Boom denotes also a cable stretched athwart the mouth of a river or harbour; with yards, topmasts, battling, or spars of wood, lashed to it, to prevent an enemy's coming in.

BOOMKIN, in sea language, a short bar of timber projecting from each bow of a ship, to extend one edge of the foresail to the windward; for which purpose there is a large block fixed to its outer end, through which the rope is passed that is fastened to the lower corner of the sail to windward, called the tack; and this being drawn tight down brings the corner of the sail close to the block, which being performed, the tack is said to be aboard. The boomkin is secured by a strong rope, which confines it downward to the ship's bow, to counteract the strain it bears from the foresail above, dragging it upward.

BOOTES, a constellation of the northern hemisphere, consisting of 23 stars according to Ptolemy's catalogue, of 28 in Tycho's, of 34 in Bayer's, of 52 in Hevelius's, and of 45 in Mr. Flamsteed's catalogue.

BOQUINIANS, in church history, a sect of heretics, so called from Boquinus their founder, who taught that Christ did not die for all mankind, but only for the faithful, and consequently was only a particular saviour.

BORACIC acid. The word borax first occurs in the works of Geber, an Arabian chymist of the 10th century. It is a name given to a species of white salt much used by various artists. Its use in soldering metals appears to have been known to Agricola.

Borax is found mixed with other substances in Thibet. It seems to exist in some lands adjacent to lakes, from which it is extracted by water, and deposited in those lakes; whence in summer, when the water is shallow, it is extracted and carried off in large lumps. Sometimes the water in these lakes is admitted into reservoirs; at the bottom of which, when the water is exhaled by the summer's heat, this salt is found. Hence it is carried to the East Indies, where it is in some measure purified and crystalized; in this state it comes to Europe, and is called tincal. In other parts of Thibet, it seems, by accounts received from China, they dig it out of the ground at the depth of about two yards, where they find it in small crystaline masses.

Though borax has been in common use for nearly three centuries, it was only in 1702, that Homberg, by distilling a mixture of borax and green vitriol, discovered the boracic acid. He called it narcotic or sedative salt, from a notion of his that it possessed the properties indicated by these names. Lemery the younger soon after discovered, that it could likewise be obtained from borax by means of the nitric and muriatic acids. Geoffroy afterward discovered, that borax contained soda; and at last Baron proved, by a number of experiments, that borax is composed of boracic acid and soda; and that it may be reproduced by combining these two substances.

The easiest method of procuring boracic acid is the following: dissolve borax in hot water, and filtre the solution; then add sulphuric acid, by little and little, till the liquid has a sensibly acid taste. Lay it aside to cool, and a great number of small shining laminated crystals will form. These are the boracic acid. They are to be washed with cold water, and drained upon brown paper.

Boracic acid, thus procured, is in the form of thin hexagonal scales, of a silvery whiteness, having some resemblance to spermaceti, and the same kind of greasy feel. It has a sourish taste at first, then makes a bitterish cooling impression, and at last leaves an agreeable sweetness. It has no smell; but when sulphuric acid is poured on it, a transient odour of musk is produced.

It reddens vegetable blues. Its specific gravity is 1.479, while in the form of scales; after it has been fused it is 1.803.

It is not altered by light. It is perfectly fixed in the fire. At a red heat it melts, and is converted into a hard transparent glass; which becomes somewhat opaque when exposed to the air, but does not attract moisture. It is much less soluble in water than any of the acids hitherto described. Boiling water scarcely dissolves 0.02 of boracic acid, and cold water a still smaller quantity. When this solution is distilled in close vessels, part of the acid evaporates along with the water, and crystalizes in the receiver. Water, therefore, renders it in some measure volatile, though it is perfectly fixed when in a state of dryness.

Neither oxygen gas, the simple combustibles, the simple incombustibles, nor the metals, produce any change upon boracic acid, as far as is at present known. It is soluble in alcohol; and alcohol containing it burns with a green flame. Paper dipped into a solution of boracic acid burns with a green flame.

Though mixed with fine powder of charcoal, it is nevertheless capable of vitrification; and with soot it melts into a black bitumen like mass, which is, however, soluble in water, and cannot be easily calcined to ashes, but sublimes in part.

With the assistance of a distilling heat it dissolves in oils, especially in mineral oils; and with these it yields fluid and solid products, which give a green colour to spirit of wine.

When boracic acid is rubbed with phosphorus, it does not prevent its inflammation; but an earthy yellow matter is left behind.

It is hardly capable of oxidizing or dissolving any of the metals except iron and zinc, and perhaps copper.

Boracic acid combines with alkalies, alkaline earths, and alumina, and most of the metallic oxides, and forms compounds which are called borats.

Sub-borat of soda, or common borax. See Borax.

BORAGO, in botany, a genus of the pentandria monogynia class and order of plants, the flower of which consists of a single petal of the length of the cup, and divided into five segments: there is no pericarpium, but the cup grows larger and inflated; and contains four seeds of a roundish figure, rugose, carinated outwardly from the point, globose at the base, and inserted into a hollow receptacle. There are five species. The leaves of borage are accounted good in removing faintness; for which reason the tops are frequently put into wine and cool tankards. Boerhaave recommends the expressed juice in all inflammatory diseases. The flowers are one of the four cordial flowers. The only officinal preparation is the conserve of the flowers.

BORASSUS, in botany, a genus of plants, of the dioecia hexandria class and order. The male and female flowers grow on separate plants, and give the plant such a different figure, that they are called by different names in the Hortus Malabaricus; the male being called ampana, and the female carimpana. The male has for the cup of

its flower the whole compound spatha, which is amentaceous and imbricated: the flower is divided into three segments, the petals being hollowed, and of an oval figure: the stamina are six thick filaments, and the antheræ are thick and striated. In the female, the cup is the same as in the male; but the petals of the flower, which is divided into three parts, in the manner of the male, are very small, of a roundish figure, and remain when the pistil, &c. fall off. The germen of the pistil is roundish; the styles are three, and small, and the stigmata are small; the fruit is a roundish obtuse berry, of a rigid structure, and containing only one cell; the seeds are three, and of an oval compressed figure. There is one species, a native of Ceylon.

BORAX, or sub-borat of soda. This salt, according to Bergmann, is composed of

39 acid
17 soda
44 water

100.

It is decomposed by the following salts, according to Fourcroy: 1 Sulphats of lime, ammonia, magnesia, glucina, alumina, zirconia. 2. Sulphats of ammonia, magnesia. 3. Nitrats of barytes, strontian, lime, ammonia, magnesia, glucina, alumina, zirconia. 4. Muriats of barytes, strontian, lime, ammonia, magnesia, glucina, alumina, zirconia. 5. Superphosphat of lime. 6. Phosphats of ammonia, magnesia, glucina, alumina, zirconia. 7. Fluats of barytes, strontian, magnesia, ammonia, glucina, alumina, zirconia.

Borax is sometimes used in medicine as an astringent. It is used as a flux for metals, and enters into the composition of some of the coloured glass pastes made in imitation of gems; but its great use is to facilitate the soldering of the more precious metals. It is employed also as a flux by mineralogists in essaying the properties of minerals by the blow pipe.

Borat of ammonia may be formed by saturating boracic acid with ammonia. It has scarcely been examined. Fourcroy affirms, that when its solution is evaporated, the ammonia is volatilized, and the acid crystalizes.

Borat of alumina may be formed by mixing together the solutions of borat of soda and sulphat of alumina. It is said to be scarcely soluble in water, and not to crystalize.

When boracic acid and silica are exposed to a strong heat, they melt together into a transparent glass. This compound has received the name of borat of silica.

BORBONIA, a genus of the decandria order, and diadelphia class of plants. The stigma is emarginated; the calyx has pointed spines; and the legumen is pointed. There are six species, all natives of warm countries. They are a kind of broom; and rise to the height of ten or twelve feet, but in Europe seldom above four or five. They are green house plants, and may be propagated by layers; but as these are generally two years before they put forth roots, the best method is by seeds, which must be procured from their native places.

BORBORITES, borboritæ, in church history, a sect of gnostics in the second century, who, besides embracing the errors of these Christians, denied the last judgment. Their name comes from βορβορος, filth, on account of a custom they had of daubing their faces and bodies with dirt and filth.

BORDARII, a term mentioned in the Doomsday inquisition; they were distinct from the servi and villani, and were of a somewhat higher rank; having a bord, or cottage, with a small parcel of land allowed to them, on condition that they should supply the lord with poultry and eggs, and other small provisions for his board and entertainment. The same term is used to denote servants employed in fetching wood, drawing water, grinding corn, cleaning yards, &c. by which they are distinguished from villani, employed in the tillage of lands.

BORDURE, in heraldry, a cutting off from within the escutcheon all round it about one fifth of the field, serving as a difference in a coat of arms, to distinguish families of the same name, or persons bearing the same coat.

If the line constituting the bordure is straight, and the bordure plain, then in blazoning you must only name the colour of the bordure.

BOREAL SIGNS, in astronomy, are the first six signs of the zodiac, or those northward of the equinoctial.

BORECOLE. See BRASSICA.

BORER, an implement invented for the purpose of searching or exploring the nature of soils. It is composed of two rods of iron, each about six feet long, and an inch in diameter, which screw into one another. By this instrument two men will easily sound the depth of twelve feet in less than a quarter of an hour, if they do not meet with many stones. Thus, without much charge, or any hazard, there is a certainty of discovering what earths are under the upper soil, and whether other substances lie concealed there, such as marl, chalk, fullers' earth, fossil shells, coals, quarries of slate or stone, oars, &c.

BORING, in mineralogy, a method of piercing the earth by a set of scooping irons, made with joints so as to be lengthened at pleasure. The mineralogist can guess where a vein of oar may lie, though there are none of the common outward signs of it upon the surface of the earth, and in this case he has recourse to boring: the scooping irons are drawn back at proper times, and the samples of earth and mineral matters they bring up are examined, to know whether it will be worth while to open a mine in the place.

BORING *of water pipes*. The method of boring water pipes is as follows. The poles of alder, which is a very useful wood in making pumps, water pipes, &c. being laid on horses or tressels of a foot in height, to rest the auger upon while they are boring, they set up a lathe to turn the least end of the poles, to fit them to the cavities of the great end of the others. They turn the small ends of the poles about five or six inches in length, to the size they intend to bore the larger ends about the same depth, *viz.* 5 or 6 inches. This is designed to make a joint to shut each pair of holes together; the concave part being the female part, and the other part the male, of the joint. In turning the male part they turn a channel in it, or a small groove at a certain distance from the end; and in the female part, they bore a small hole to fit over this channel. This being done, they bore the poles through; and to prevent them from boring out at the side, they stick great nails at each end to be a guide in boring. It is usual, however, to bore them at both ends; so that if a pole is crooked one way, they can bore it through and not spoil it.

The operation is now performed with a horse mill, as at Dorset stairs, for the new river company. See PIPE BORING.

BOROUGH, Burrough, Borow, or Burgh, a corporation or town which is not a city. The word in its original signification meant a company consisting of ten families, which were bound together as each other's pledge. Afterward borough came to signify a town, having a wall or some kind of enclosure round it; and all places which formerly had the name of borough, it is said, were fortified, or fenced in some shape or other.

The name is now particularly appropriated to such towns or villages as send burgesses or representatives to parliament, whether they are incorporated or not. They are distinguished into those by charter or statute, and those by prescription or custom. The number in England and Wales, including cities and cinque ports, which elect members, is 215; some of which send one, and some two representatives.

Royal Boroughs, in Scotland, are corporations made for the advantage of trade, by charters granted by several of their kings, having the privilege of sending commissioners to represent them in parliament, besides other peculiar immunities. They form a body of themselves, and send commissioners each to an annual convention at Edinburgh, to consult the benefit of trade and their general interest.

Borough English, a customary descent of lands or tenements, in certain places, by which they descend to the youngest instead of the eldest son; or, if the owner has no issue, to the younger instead of the elder brother. This custom goes with the land, although there be a devise or feoffment at the common law to the contrary. The reason of this custom, says Littleton, is because the youngest is presumed, in law, to be least able to provide for himself.

Borough head. See Headborough.

BORRELLISTS, in church history, a Christian sect in Holland. They are a kind of anabaptists, but they have some very particular opinions. They reject the use of churches, of sacraments, public prayer, and all other external acts of worship.

BORRERA, in botany, a genus of the class cryptogamia, order sichenes; of this there are four species, natives of America. 1. B. Ciliaris; 2. B. Leucomela; 3. B. Chrysophthalma; 4. B. Exilis. (*a*.)

BORYA, in botany, a genus of the class dioecia, order diandria; the calyx four leaved, corolla none, drupa 1 sperma: there are three species; *viz*. 1. B. Porulosa, a native of Florida. 2. B. Ligustrina, a native of Tennessee. 4. B. Accuminata, a native of Carolina and Georgia.

BOS, in zoology, the ox, a genus of quadrupeds of the order of pecora. The generic character is, horns concave, turned outward, lunated, smooth; front teeth eight in the lower jaw; canine teeth none.

1st. The bison, from which the several races of common cattle have been gradually derived, is found wild in many parts both of the old and new continents; inhabiting woody regions, and arriving at a size far larger than that of the domestic or cultivated animal. In this its native state of wildness, the bison is distinguished, not only by his size, but by the superior depth and shagginess of his hair; which about the head, neck, and shoulders, is sometimes of such a length as almost to touch the ground: his horns are rather short, sharp pointed, extremely strong, and stand distant from each other at their bases, like those of the common bull. His colour is sometimes of a dark blackish brown, and sometimes rufous brown; his eyes large and fierce; his limbs extremely strong, and his whole aspect in degree savage and gloomy. See Plate XVI. Nat. Hist. fig. 59.

The principal European regions where this animal is at present found, are the marshy forests of Poland, the Carpathian mountains, and Lithuania. Its chief Asiatic residence is the neighbourhood of mount Caucasus; but it is also found in other parts of the Asiatic world.

The American bison seems to differ in no respect from the European, except in being more shaggy, and having a more protuberant bunch or fleshy substance over the shoulders.

It grows to a vast size, and has been found to weigh sixteen hundred, and even two thousand four hundred pounds; and the strongest man cannot lift one of the skins from the ground.

These were the only animals which bore any affinity to the European cattle, on the first discovery of the American continent; and might have been made to answer every purpose of the European cow; but the natives, being in a savage state, and living chiefly by chase, had never attempted the domestication of the animal.

2d. Common ox. This is, in reality, the bison reduced to a domestic state; in which, in different parts of the world, it runs into as many varieties as the sheep; differing widely in size, form, and colour, according to climate and other circumstances. Its importance in this its domestic state needs not be mentioned. Formerly the ox constituted the whole riches of mankind; and he is still the basis of the wealth of nations, which subsist and flourish in proportion to the cultivation of their lands and the number of their cattle. See Plate XVI. Nat. Hist. fig. 54, 55.

The British breed of horned cattle has been so much improved by a foreign mixture, that it is difficult to point out the original kind of these islands. Those which may be supposed to have been purely British, are far inferior in size to those of the northern parts of the continent. The cattle of the highlands of Scotland are exceedingly small; and many of them, males as well as females, are hornless. The Welsh runts are much larger: the black cattle of Cornwall are of the same size with the last. The large kind that is now cultivated throughout most parts of Great Britain, are either entirely of a foreign extraction, or our own improved by a cross with the foreign kind. The Lincolnshire kind derive their size from the Holstein breed; and the large hornless cattle that are bred in some parts of England came originally from Poland.

3d. Indian ox. This variety is found in many parts of India, also in the Indian and African islands, and particularly in Madagascar. It is of a reddish colour, of a very large size, and is distinguished by a very large protuberance above the shoulders.

4th. Zebu. This variety resembles the preceding, but is extremely small, being found in some parts of India of a size scarcely larger than a great dog. In colour it differs like the common cattle; being either gray, brown, white, &c. or variously spotted. See Plate XVI. Nat. Hist. fig. 60.

5th. Loose horned ox. This is said to be found in Abyssinia and Madagascar, and to be distinguished by

pendulous ears, and horns attached only to the skin, so as to hang down on each side.

6. Boury. Of the size of a camel, and of a snowy whiteness, with a protuberance on the back. Native of Madagascar, and some other islands, called by the name of Boury.

7. Tinian ox. Of a white colour, with black ears. Inhabits the island of Tinian.

II. Bos Arnee. Ox with upright lunated horns, flat and wrinkled on their upper surface.

This is an Indian species, known chiefly from its vast horns, which are sometimes seen in museums, and from Indian paintings, in which it is occasionally represented. It is said to have been met with by a British officer, in the woods above Bengal, and to have been about fourteen feet high, which is to be understood of the measure from the hoofs to the top of the horns. It partakes of the form of the horse, the bull, and the deer, and is a very bold and daring animal.

III. Bos Babylus, or Buffalo, ox with horns lying backward, turning inward, and flat on the fore part. See Plate Nat. Hist. fig. 61.

In its general appearance, the buffalo is so nearly allied to the common ox, that without an attentive examination it might pass for a variety of the same animal. It differs, however, in the form of its horns, and in some particulars relative to its internal structure. The buffalo is rather superior in size to the common ox, the head larger in proportion; the forehead higher; the muzzle of a longer form, but at the same time broad and square. But it is principally the form of the horns that distinguishes the buffalo. They are large, and of a compressed or depressed form, with the exterior edge sharp. The buffalo has an appearance of great strength, and a more ferocious or malignant aspect than the bull; owing to the convexity of his forehead, the smallness of his eyes, the flatness of his muzzle, and the flatter and more inclined position of his horns. The general or prevailing colour of the buffalo is blackish, except the hair on the top of the forehead, and that at the tip of the tail, which is of a yellowish white: the skin itself is also of a black colour; and from this general cast it is but very seldom observed to vary.

As the buffalo in his domesticated state is, in general, larger and stronger than the ox, he is employed with advantage in different kinds of labour. Buffaloes are made to draw heavy loads, and are commonly directed and restrained by means of a ring passed through the nose. Two buffaloes yoked, or rather chained to a cart, are able to draw as much as four strong horses. As they carry their neck and head low, the whole weight of their body is employed in drawing; and their mass much surpasses that of a labouring horse. In its habits the buffalo is much less cleanly than the ox; delighting to wallow in the mud; and, next to the hog, may be considered as the dirtiest of domesticated quadrupeds. His voice is deeper, more uncouth and hideous, than that of the bull. The milk of the female buffalo is said by some authors to be not so good as that of the cow; but it is more plentiful, and is used for the purposes of the dairy in the warmer regions. Italy is the country where buffaloes are at present most common in a domesticated state; being used, as in India, both for the dairy and for draught. The district of the Pontine marshes is the spot which may be considered as their principal station. In India this animal is occasionly used for the saddle, as a substitute for the horse.

The buffalo, like other animals of this genus, admits of varieties as to size and figure. Of these the most remarkable is the small naked Indian buffalo of Mr. Pennant, which is the size of a runt, with a nearly naked body, thinly beset with bristly hair: the rump and thighs quite bare; the first being marked on each side with dusky stripes pointing downward, the last with two transverse stripes: the horns compressed sideways, taper, and sharp at the point. It is a native of India.

Another variety, still smaller, is said to occur in the mountains of the Celebes, which are full of caverns. This variety is of the size of a middling sheep, and is seen in small herds, very wild, and difficult to be taken; and even in confinement are so fierce, that Mr. Pennant records an instance of fourteen stags being destroyed in the space of a single night by one of these animals which was kept in the same paddock.

IV. Bos Moschatus, or musk ox, having very long pendent hair, and horns (in the male approximated at the base) bending inward and downward, and outward at the tips.

It is a native of North America, where it appears to be a very local animal; being found first in the tract between Churchill river and that of the Seals, on the west side of Hudson's bay; and is very numerous between the latitudes 66 and 73 north, which is as far as any tribes of Indians go.

This animal is but of small size, being rather lower than the deer, but larger or thicker in body. The hair, in the male, is of a dusky red colour, extremely fine, and so long as to trail on the ground, and renders the animal a seemingly shapeless mass, without distinction of head or tail: the legs are very short; the shoulders rise into a lump, and the tail is very short, being a kind of stump of a few inches only, with very long hairs. Beneath the hair, on all parts of the animal, is an extremely fine cinereous wool, which is said to be more beautiful than silk when manufactured into stockings and other articles. The horns are closely united at the base, bending inward and downward; but turning outward toward the tips, which are very sharp: near the base the horns are two feet in girth, but are only two feet long when measured along the curvature: the weight of a pair, separated from the head, is sometimes sixty pounds.

The cow, or female, differs from the male in having the horns much smaller, and placed at the distance of nine inches from each other at the base.

The general colour of the cow is black, except that the legs are whitish, and between the horns there is a bed of white hair intermixed with rust colour; a dusky mane, or elevated ridge of hair, runs along the back, and on the middle of the back is an oblong patch or bed of pure white.

These creatures delight most in rocky and barren mountains, and seldom frequent the wooded parts of the country. They run nimbly, and are very active in climbing the rocks. Their flesh tastes very strongly of musk; and the heart in particular is said to be so thoroughly impregnated with the flavour as to be scarcely eatable. The flesh, however, is supposed to be very wholesome, and has been found a speedy restorative to sickly crews who have made it their food.

V. Bos Grunniens, or Yak, having with cylindric horns curving outward, very long pendent hair, and ex-

tremely villose horse like tail, is about the height of an English bull, which he resembles in the general figure of the body, head, and legs; it is covered all over with a thick coat of long hair. The head is rather short, crowned with two smooth round horns, which, tapering from the root upward, terminate in sharp points: they are arched inward, bending toward each other, but near the extremities are a little turned back.

They are a very valuable property to the tribes of itinerant Tartars, called Duckba, who live in tents and tend them from place to place: they at the same time afford their herdsmen an easy mode of conveyance, a good covering, and wholesome subsistence. They are never employed in agriculture, but are extremely useful as beasts of burthen; for they are strong, sure footed, and carry a great weight. Tents and ropes are manufactured of their hair; and amongst the humbler ranks of herdsmen, caps and jackets are made of their skins. Their tails are esteemed throughout the East, as far as luxury and parade have any influence on the manners of the people. In India no man of fashion ever goes out, or sits in form at home, without two chowrabadars, or brushers, attending him, each furnished with one of these tails mounted on silver or ivory handles, to brush away the flies. The Chinese dye them of a beautiful red, and wear them as tufts to their summer bonnets.

The yak is the most fearful of animals, and very swift; but when chased by men or dogs, and finding itself nearly overtaken, it will face its pursuers, and hide its hind parts in some bush, and wait for them; imagining that if it could conceal its tail, which was the object they were in search of, it would escape unhurt.

VI. Bos Caffer, or cape ox, having the horns very broad at the base, then spreading downward, next upward, and at the tips curving inward; inhabits the interior parts of Africa, north of the cape of Good Hope, and is greatly superior in size to the largest English ox. It is of a very strong and muscular form, with a fierce and malevolent aspect. Its colour is a deep cinereous brown: the hair on the body is rather short, but that on the head and breast very long, coarse, and black, hanging down the dewlap, like that of a bison: from the hind part of the head to the middle of the back is also a loose black mane: the tail is nearly naked at the base; the remainder being covered with long loose hair.

These animals are found in large herds in the desert parts beyond the Cape; and if met in the narrow parts of woods, are extremely dangerous, rushing suddenly on the traveller, goring and trampling both man and horse under foot. It is also said that they will often strip off the skin of such animals as they have killed, by licking them with their rough tongues, as recorded by some of the ancient authors of the bison. The urcus is the same animal with the common bull in its natural and wild state. See Plate Nat. Hist. fig. 58. See also figs. 56, and 57.

BOSCOI, or Bosci, a tribe of monks in Palestine, who fed on grass like the beasts of the field. They are ranked among the number of Adamites, on account of the little care they took about provision; when they were hungry, they went into the fields, each with his knife in his hand, and gathered and ate what they could find.

BOSEA, golden rod tree: a genus of the digynia order, and pentandria class of plants; and in the natural method ranking under the 53d order, scabridæ. The calyx is pentaphyllous; there is no corolla, and the berry is monospermous. Of this genus there is but one species, *viz.*

Bosea yervamora. It is a native of the Canary and Caribbee islands, and has been long an inhabitant of the British botanic gardens. It is a pretty strong woody shrub, growing with a stem as large as a man's leg. It may be propagated by cuttings planted in spring; and the plants must be housed in winter.

BOSS, among bricklayers, denotes a wooden utensil in which the mortar used in tiling is to be put. It has an iron hook by which it may be hung on the laths or on the ladder.

BOSSAGE, in architecture, a term used for any stone that has a projecture, and is laid rough in a building to be afterward carved into mouldings, capitals, coats of arms. It is also that which is otherwise called rustic work, and consists of stones which advance beyond the naked or level of the building, by reason of indentures or channels left in the joinings.

BOSSIACA heterophylla, in botany, a plant of the diadelphia, decandria class and order; the calyx is two lipped, heart shaped; carina two petals; a shrub, native of New Holland. (*b.*)

BOSTANGIS, in the Turkish affairs, persons employed in the garden of the seraglio, out of whose number are collected those who are to row in the grand seignior's brigantines.

BOSTRYCHITES *lapis*, a name given to a stone supposed to contain women's hair included in it. Some have understood by it those pieces of crystal which have accidental foulness in them resembling hair; others call by this name those German agates which contain either the confervæ or other capillary water plants. It is also a name given to a species of pyrites, the irradiations of which were supposed to imitate hair.

BOTANY, from Βοτανη, Greek, an herb or plant, formerly implied a knowledge of the nature, uses, and cultivation of plants. In our accounts of the different genera, we have endeavoured to combine these three objects. But as a modern science, botany chiefly applies to the classification of plants; or that systematic arrangement by which, from general marks or characters, the botanist is enabled, first to trace the class, next the order, then the genus, and last of all the species, to which any plant he meets with belongs.

Various systems have been invented for the classification of the vegetable tribes; but that of Linnæus, as the simplest and most decisive, has superseded them all. It is founded on the sexual system, or that which supposes all plants to have male and female parts of generation; a system which there is every reason to believe physiologically true, but which in that view will be more properly treated of under the article Physiology of Plants.

Sect. I. *Of the parts of plants.*

The principal outlines of a plant are thus delineated by Linnæus:

A plant consists of a root, trunk, leaves, props, fructification, and inflorescence, to which may be added the habit.

I. The root consists of two parts, *viz.* the caudex and

the radicula, distinguished according to shape, direction, duration, &c.

1. Caudex, the stump, is the body or knob of the root, from which the trunk and branches ascend, and the fibrous roots descend, and in different plants is either solid, bulbous, or tuberous. Solid, as in trees, shrubs, and many of the herbs. Bulbous is explained under HYBERNACULUM. Tuberous knobs are also solid and hard, containing one or more embryos or eyes. They are either only one knob, as turnip, carrot, &c. containing only one eye at the top; or consist of many knobs connected together by slender fibres, as in potatoes, Jerusalem artichokes, &c. each containing many eyes dispersed over the surface; and are either pitted, when the eyes lie inward, as in potatoes, &c. or tuberculated, containing the eyes outward, as in Jerusalem artichokes, &c. In tuberous knobs, the fibres or stringy parts issue from every part of the surface, which is an essential difference from bulbous knobs, where they are confined to the caudex of the bulb only, and are the true and genuine roots, the bulb itself being only a large bud under ground. Those tuberous knobs with only one eye, differ as to duration, but are in general biennial; those with many eyes are perennial; both seem to be produced by the nutriment of the stemlike buds, and not by the fibrous roots, for the stem is first formed and becomes strong, and as it grows to maturity, the tuberous knobs increase.

2. Radicula, a little root, is the string or fibrous part of the root, descending from the caudex: it is really the principal and essential part of every root, and by which the nourishment is drawn from the earth for the support of the plant.

II. The trunk rises immediately from the caudex; and produces the leaves, flowers and fruit. It is either herbaceous, shrubby, or arborescent; and is distinguished according to its shape, substance, surface, &c. as follows:

1. Caulis, a stalk or stem, is the main trunk which elevates the leaves and fructification, and is applied to trees, shrubs, and herbs. It is denominated simple when it does not divide, and compound when it is divided into branches.

2. Culmus, a straw or haulm, is the proper trunk of grasses, and also elevates both the leaves and fructification. It is sometimes jointed, and sometimes not: it is also sometimes round and sometimes angular.

3. Scapus, a stalk, is an herbaceous trunk which elevates the fructification, but not the leaves; that is, it is a stalk proceeding immediately from the root, and terminated by the flowers, as in narcissus, hyacinth, &c.

4. Stipes, a trunk, used by Linnæus for the trunk of mushrooms, as also for that slender thread or footstalk which elevates the feathery or hairy down with which some seeds are furnished, and connects it with the seed.

III. The leaves are either simple or compound, and are distinguished by their figure, situation, insertion, number, divisions, &c.

1. A simple leaf is such as adheres to the branch singly, or whose footstalk is terminated by a single expansion, not parted to the middle rib, and is determined by its shape, surface, and divisions.

2. A compound leaf is such whose footstalk is furnished with several separate simple expansions, or whose divisions extend to the middle rib, now called a common petiole or footstalk, supporting several lobes or little simple leaves, of which the compound leaf consists. They are distinguished by shape, &c. and the form by which they are attached to the common footsalk, as palmated, winged, feathered, &c. Sometimes leaves are twice or more compounded, which divisions admit of many modifications, and give rise to as great variety of terms. It may sometimes be difficult, at first sight, to know a common footstalk to a compound leaf from a branch; but a common footstalk, where it issues from the branch, is either flat or hollow on one side, and convex on the other; whereas branches are alike on both sides, whether round, flat, or angular: again, buds are never found at the angles formed by the lobes of a compound leaf with the footstalk, but at the angles formed by the footstalk of the whole compound leaf and the stem; and it may always be certainly distinguished by its falling off with the little leaves which it supports. The manner or place in which leaves are attached to the plant, is called the determination of leaves, and is distinguished by several terms, according to number, disposition, insertion, figure, &c. For the different kinds of leaves, see Plates XVII, XVIII, XIX. Botany.

IV. The props, fulcra, a term used to express those external parts which strengthen, support, or defend, the plants on which they are found, or serve to facilitate some necessary secretion, are as follow:

1. Petiolus, the footstalk or support of a leaf.

2. Pedunculus, the footstalk or support of a flower.

3. Stipula, haulm or husk, a sort of scale or small leaf stationed on most plants, when present, on each side the base of the footstalk of leaves and flowers, at the first appearance, for the purpose of support. They are placed either single or double, and sometimes on the inside, as in the fig and mulberry; or on the outside, as in the birch, lime, and papilionaceous flowers. They are also either sitting, extended downward, or sheathing along the stem, as in the plane tree. As to duration, they sometimes fall before the leaves, and sometimes are equally persistent. They often afford a good distinction for the species.

4. Cirrhus, a clasper or tendril, is the fine spiral string or fibre by which plants fasten themselves to some other body for support. They are sometimes placed opposite to the leaves; sometimes at the side of the footstalks of the leaves; sometimes they issue from the leaves themselves; and sometimes they put out roots, as in ivy, &c.

5. Pubes, a term applied to the hair, down, wool, beard, bristles, glands, and several other appearances on different parts of plants, serving the double purpose of defence and vessels of secretion.

6. Arma, the defensive weapons of plants, as thorns, prickles, &c.

7. Bracteæ, the floral leaves, mean not only those leaves situated on the stalk nearest to the lower parts of the flower, but those which sometimes terminate the flower stalk, being composed of large bracteæ, resembling a bush of hair. They are then called bracteæ comosæ, as in crown imperial, lavender, and some species of sage.

V. The fructification, or mode of fruit bearing, consists of the calyx, corolla, stamina, pistillum, pericarpium, semina, and receptaculum, which are afterward explained.

VI. The inflorescence, or mode by which flowers are joined to their several peduncles, whether common or partial.

i. A flower, in the sexual system, has a very different signification from the same term of former botanists; for if the antheræ and stigma are present, though the calyx, corolla, filaments of the stamina, and style of the pistillum, be wanting, it is still a flower; and if all the parts are present, it is a complete flower. The seed also constitutes the fruit, whether there is a pericarpium or not.

ii. Complete flowers are either simple or aggregate; simple, when no part of the fructification is common to many flowers or florets, but is confined to one only; aggregate, when the flower consists of many florets collected into a head, by means of some part of the fructification common to them all, as by a common receptacle, or common calyx; as in dipsacus, scabiosa, &c. From the different structure, disposition, and other circumstances of the receptacle or calyx, being the only part common to aggregate flowers, arise seven subdivisions.

1. Aggregate flowers, properly so called, are formed by the union of several lesser flowers, placed on partial peduncles on a common dilated receptacle, and within a common perianthium; and in those flowers where each floret has its proper calyx, that is also a perianthium. A flower is said to be radiate, when the florets in the radius or circumference differ from those in the disk; in which case they are generally larger, and are called semiflorets, from their difference in form, and in distinction from those of the disk, which are called proper florets; and they also differ as to sex, which gives rise to several of the orders in the class syngenesia, which contains the compound flowers.

2. Compound aggregate flowers consist also of several florets, placed sitting, or without partial peduncles, on a common dilated receptacle, and within a common perianthium; and where each floret has its proper calyx, it is also a perianthium. Compound flowers also admit of a further description, *viz.* each floret consists of a single petal, with generally five divisions, and having five stamina distinct at the base, but united at the top by the antheræ into a cylinder, through which passes the style of the pistillum, longer than the stamina, and crowned by a stigma with two divisions rolled backward, and having a single seed placed upon the receptacle under each floret. This is the general character of a compound flower, to which there are a few exceptions; it also differs when the flower is radiate; but the essential character of a regular floret consists in the antheræ being united so as to form a cylinder, and having a single seed placed upon the receptacle under each floret.

3. Umbellate aggregatæ are when the flower consists of many florets placed on fastigiate peduncles proceeding from the same stem or receptacle, and which, though of different lengths, rise to such a height as to form a regular head or umbel, whether flat, convex, or concave. Both the common and partial calyx Linnæus calls an involucrum. It is called a simple umbel when it has no lesser divisions; a compound umbel when each peduncle is subdivided at its extremity into many lesser peduncles for supporting the flowers, so as to form several little umbellas, uniting in one head: the whole together is called an universal umbel, and the little umbellas are called partial umbels. In some genera that have radiated umbels, the florets of the centre and those of the circumference differ both as to sex and size; but in general each have five petals, five stamina, and two styles; or one that is bifid, with a germen placed beneath, and two naked seeds, which when ripe, separate below, but remain connected at the top.

4. Cymous aggregate, from cyma, a sprout, called by Linnæus a receptacle, is when several fastigiate peduncles proceed from the same centre like the umbel, and rise to nearly an even height; but unlike the umbel, the secondary or partial peduncles proceed without any regular order, as in sambucus, viburnum, &c.

5. Amentaceous aggregate are such flowers as have a long common receptacle, along which are disposed squamæ or scales, which form that sort of calyx called amentum, or catkin, as in corylus, pinus, juglans, &c. Amentaceous flowers generally want the petals, and all of them are of the classes monoecia and dioecia.

6. Glumose aggregate are such flowers as proceed from a common husky calyx belonging to grasses, called gluma; many of which are placed on a common receptacle called rachis, collecting the florets into the spike, as triticum, hordeum, secale, lolium, &c.

7. Spadiceous aggregate are also such flowers as have a common receptacle protruded from within a common calyx, called spatha, along which are disposed several florets. Such a receptacle is called spadix; and is either branched, as in phœnix, or simple, as in narcissus, &c. In this last case, the florets may be disposed either all round it, as in calla, dracontium, pothos, &c. on the lower side of it, as in arum, &c. or in two sides, as in zostera, &c. These flowers have generally no partial calyx.

Under the head of inflorescence might also be mentioned the sexes of plants. There are, besides the above, several other modes of flowering, properly so called, that come under the general term inflorescence, and often afford the best marks to discriminate the species. They are chiefly expressed as follows:

1. Verticillus, a whorl, when the flowers are placed in whorls at each joint round the common stalk: they have very short partial peduncles, are all of the labiated kind, and have either two or four stamina, and four naked seeds, as in salvia, marubium, mentha, &c. A verticil has several distinctions, as naked, bracted, &c. and all those genera with four stamina are of the class didynamia, as is seen in mint, thyme, &c.

2. Capitulum, a little head, is when many flowers are connected into nearly a globular form or head, on the summit of the common stalk, sometimes with and sometimes without partial peduncles, as in gomphrena, &c. and is distinguished by its shape and other circumstances. Under capitulum is now introduced the term fasciculus, a little bundle, which was formerly considered as distinct. It means when the peduncles are erect, parallel, approaching each other, and raised to the same height, as in sweetwilliam, where they generally proceed from different parts of the common stalk opposite to each other.

3. Spica, a spike, is when the flowers, having no partial peduncles, are arranged alternately around a common simple peduncle. It is called spica secunda, a single

rowed spike, when the flowers are all turned one way, following each other; and spica disticha, a double rowed spike, when the flowers stand pointing two ways, as in lolium, &c. and it is distinguished by shape and other circumstances.

4. Corymbus, a cluster of ivy berries, when the lesser peduncles of the flowers proceed from different parts of the common peduncle or stalk; and though of unequal lengths, and sometimes single, sometimes branched, yet form a regular surface at the top, as in the siliquose plants. The corymbus may be supposed to be formed from a spike, by adding partial peduncles to the flowers, and seems to be the mean between the racemus and umbella, the peduncles rising gradually from different parts of the common stalk, like those of the raceme, and proceeding to a proportionable height like those of the umbel.

5. Thyrsus, a young stalk, a mode of flowering resembling the cone of a pine. Linnæus defines it a panicle contracted into an ovate or egg shaped form; the lower peduncles, which are longer, horizontally; and the upper, which are shorter, mount vertically, as syringa, &c.

Racemus, a bunch of grapes, is when the flowers are placed on short partial peduncles, proceeding as little lateral branches from and along the common peduncle. It resembles a spike in having the flowers placed along a common peduncle, but differs from it in having partial peduncles: it also differs from a corymbus in the shortness and equal length of its peduncles, not forming a regular surface at the top, as in ribes rubrum, vitis, &c.

6. Panicula, the tuft upon reeds, is when the flowers are dispersed upon peduncles variously subdivided; or it is a sort of branching spike, composed of several smaller spikes, attached along a common peduncle, as in avena, panicum, and several other grasses, and many other plants. When the partial peduncles diverge and hang loose, it is called a diffuse, and when they converge, it is called a close, panicle.

7. Axillares, such flowers as proceed from the angle formed by the leaf and the stem, as is most common.

8. Terminales, such flowers as terminate the stalk or branch. Every other mode of flowering is called the inflorescence, whether opposite to the leaves, lateral, single, double, erect, bending, &c.

Luxuriant, or double flowers, are considered only as varieties. A luxuriant flower is supposed generally to be owing to superabundant nourishment; the luxuriant part is generally the corolla, but sometimes the calyx also. There are three degrees of luxuriant flowers, *viz.* 1. multiplicatus; 2. plenus; and 3. prolifer.

1. Flos multiplicatus is when the petals of the corolla are only so far multiplied as to exclude part of the stamina; and is called duplicate, triplicate, quadruplicate, &c. according to the number of rows of petals.

2. Flos plenus is when the corolla is so much multiplied as to exclude all the stamina, which is occasioned by the stamina turning petals, and the flower is often so crowded as to exclude or choke the pistillum also. Therefore, as the essential parts of generation are thus wholly or in part destroyed, the plants become barren and imperfect, and no seed, or very little, can be expected from them. Flowers with one petal are not very subject to fulness; when they are, it generally arises from an increase of the divisions of the petal. It is most usual in flowers of many petals, where it arises various ways; sometimes by multiplication of the petals only, sometimes of the calyx or nectarium, and sometimes of all. Compound flowers are also subject to luxuriance, arising several ways.

3. Flos prolifer is when one flower grows out of another; this generally happens in full flowers, from their greater luxuriancy. In simple flowers it rises from the centre, and proceeds from the pistillum, shooting up into another flower, standing on a single footstalk. In aggregate flowers, properly so called, many footstalked flowers are produced out of one common calyx. In umbellate flowers, a second umbel proceeds from the centre of the first umbel, producing little umbels, which by a greater exertion of luxuriancy, may produce others with little umbels, and thus may produce several heads of flowers, each growing out of that immediately below it, furnished with little umbels variously compounded. A prolific flower is also called leafy, frondosus, when it produces branches with flowers and leaves; which, though rare, sometimes happens in rosa, anemone, monarda, and others. As in luxuriant flowers many parts of the natural character are deficient in the whole, or in any part, they can only be distinguished by the general habit, and by such parts as remain in the natural state; as very often by the calyx, and in the polypetalous flowers, the lowest series or rows of petals remain the same, as in rosa, papaver, nigella, &c.

4. Flos mutilatus is the opposite imperfection, being such a flower as occasionally is deprived of all, or the greatest part of the petals, yet bears seeds, as in some species of tussilago, campanula, &c. This term is opposed to luxuriance, and is supposed by Linnæus to be caused by a defect of heat, though it may also happen from other causes.

VII. The habit of plants, by which ancient botanists meant the whole external appearance of every part, whereby they were arranged in their several systems, is by Linnæus applied to the agreement of plants of the same genus, or natural order, chiefly in the following circumstances:

1. Gemmation. The structure and disposition of the bulb; as solid, coated, scaly, stem. Also of the bud; its origin petioled, stipuled, cortical; its contents leafy, floral, common.

2. Vernation. The complication of the leaves within the bud, as conduplicate or doubled together; convolute or rolled together; involute or rolled in; revolute or rolled back; imbricated or tiled; equitant or riding; obvolute or rolled against each other; plaited or folded over; spiral or coiled like a watch spring, one end in the centre.

3. Æstivation. The state of the bud in summer, as convolute, imbricated, conduplicate, valved, unequally valved.

4. Tortion. The twisting or bending of the parts, as uniform, dissimilar, from the right, from the left, reciprocal, resupine, spiral.

5. Nuptials. Male, female, androgynous, hermaphrodite.

6. Semination. The shape and other circumstances of the seed, as tail, wing, tuft, awn, hooks, gluten, curvature. Also of the pericarpium; as berrying, inflation, viscosity, elasticity, structure.

7. Placentation. The number and disposition of the cotyledons; or if wanting.

8. Variation. Of colour, size, pubescence, age. 1. External: plaited, bundled, broad leaved, curled, awn-

less. 2. Internal: mutilated, great flowered, luxuriant, crested, viviparous, bulb bearing. By variation or variety, are meant such differences as are only incidental to vegetables, and are not found constant and unchangeable; that is, where plants raised from the same seed, by some accidental cause differ in their form and appearance from the true character of the species to which they belong; which cause being removed, the plant is restored to its true specific character; and these incidental varieties chiefly arise by difference of soil or culture in some of the above circumstances. And though it is as necessary to collect varieties under their proper species, as the species under their proper genera, yet it is often more difficult: 1st, from the difficulty of ascertaining the genus, and, 2dly, from the danger of confounding the species; and sometimes some parts of the specific character itself are also subject to variety, particularly the leaves; though in general the true specific character is constant and unchangeable, arising only from circumstances in which plants of the same genus are found to disagree, which distinctions are commonly taken with most certainty from the parts explained in this section.

VIII. The hybernaculum, winter lodgement, is that part of a plant which defends the embryo or future shoot from external injuries during the winter, and is either a bulb or a bud.

i. A bulb, bulbus, is a large sort of bud produced under ground, placed upon the caudex of certain herbaceous plants, hence called bulbous plants, all of which are perennial, that is, perpetuated by their bulbs or ground buds, as well as by seeds; they are therefore improperly called roots, being only the hybernacle of the future shoot. Bulbs are of the following sorts:

1. Squamous, consisting of scales laid over each other like tiles, as in the lily.

2. Solid, consisting of a close substance, as in tulips.

3. Coated, consisting of many coats infolding each other, as in onions.

4. Cauline, produced not only from the sides of the principal bulb, called a sucker or offset, but from other parts of the stem; as in crow or wild garlic, and in some species of onion, hence called bulbiferous, where they are produced at the origin of the umbel of flowers.

ii. A bud, gemma, is the embryo of the plant, seated upon the stem of the branches, covered with scales. In general there are three sorts of buds: that containing the flower only, as in poplar, ash, &c. where the leaf buds and flower buds are distinct; that containing the leaves only, as in birch, &c. and that containing both flower and leaves, as in the generality of plants; and these last sometimes contain leaves and male flowers, sometimes leaves and female flowers, sometimes leaves and hermaphrodite flowers. Annual plants are only renewed from seeds; and several other plants, both trees and shrubs, have no winter buds. It is also observed in hot countries, that few plants have buds; or at least that they are without that scaly covering which seems essential to a bud, and constitutes the hybernacle; instead whereof are protruded small feather like branches from the wings of the leaves, defence and protection from cold not being necessary; whereas in cold countries most plants have buds, which are wrapped up all the winter, in readiness to greet the approaching spring.

Analogous to the protection afforded by the buds, is the sleep of plants, which, according to Linnæus, happens various ways; as by converging, including, surrounding, fortifying, conduplicating, involving, diverging, depending, inverting, imbricating. This disposition in plants is very remarkable in chickweed, pimpernell, dandelion, goat's beard, &c. which expand their flowers only at certain times of the day, and shut them up at the approach of night or a storm; from which may be prognosticated a change of weather. In many plants, not only the flowers, but the young shoots, are defended from external injuries by the nearest leaves converging and enclosing the tender rudiments. Thus we have delineated the principal outlines of plants; but a more particular description of those parts which serve chiefly to characterize the different classes, orders, genera, and species, will be given in the following sections, particularly

Sect. II. *Of the classes of plants.*

The flowers of plants Linnæus very properly made the sole foundation of his beautiful system of botany. Being the same in all parts of the globe capable of producing plants, the classification founded upon them affords a kind of universal language, so to speak, to botanists, whereby they can no longer mistake each other's meaning, as has unfortunately been the case, less or more, with almost all former botanical systems.

Flowers, in respect of sex, are distinguished into male, female, hermaphrodite, and neuter. Male flowers are such as have only the stamina, as in the classes monoecia, dioecia, and polygamia. Female flowers are such as have only the pistilla, as in the same classes. Hermaphrodite flowers are such as have both the stamina and pistilla in the same flower, as in almost all the other classes: hermaphrodites are also distinguished into male hermaphrodites, when the female is ineffectual; and female hermaphrodites, when the male is ineffectual. Neuter flowers are such as have neither stamina nor pistilla perfect.

The plants themselves also take a denomination from the sex of their flowers. Male plants are such as bear male flowers only; female plants bear female flowers only; hermaphrodite plants bear hermaphrodite flowers only. Androgynous plants are such as bear male and female flowers, distinct upon the same root, as in the class monoecia. Polygamous plants are such as bear hermaphrodite flowers, and male or female flowers, or both distinct, on the same or on different roots.

When on the same root, the flowers are either male hermaphrodites and female hermaphrodites; or hermaphrodites and male; or hermaphrodites and female, distinct: if on different roots, the flowers are either hermaphrodites and male; hermaphrodites and female; hermaphrodites and both male and female; or are androgynous and male; and sometimes androgynous and male and female on three distinct plants.

TABLE OF THE CLASSES.

1. Monandria, *i.e.* one male or stamen in an hermaphrodite flower.
2. Diandria, *i.e.* two stamina,
3. Triandria, — three ditto.
4. Tetrandria, — four ditto.
5. Pentandria, — five ditto.
6. Hexandria, — six ditto.

7. Heptandria, *i.e.* seven ditto.
8. Octandria, — eight ditto.
9. Enneandria, — nine ditto.
10. Decandria, — ten ditto.
11. Dodecandria, — twelve ditto.
12. Icosandria, — twenty or more ditto, inserted into the calyx.
13. Polyandria, *i.e.* all above twenty stamina inserted into the receptacle.
14. Didynamia, *i.e.* four stamina, two long and two short.
15. Tetradynamia, *i.e.* six stamina, four long and two short.
16. Monadelphia, the stamina united into one body by the filaments.
17. Diadelphia, the stamina united into two bodies by the filaments.
18. Polyadelphia, the stamina united into three or more bodies by the filaments.
19. Syngenesia, the stamina united in a cylindrical form by the antheræ.
20. Gynandria, the stamina inserted into the pistillum.
21. Monoecia, male and female flowers distinct, in the same plant.
22. Dioecia, males and females in different plants, of the same species.
23. Polygamia, male, female, and hermaphrodite flowers in the same or different plants.
24. Cryptogamia, the flowers invisible, so that they cannot be ranked according to the parts of fructification, or distinctly described.

These 24 classes comprehend every known genus and species. It is easy to class a plant belonging to any of the first 11 classes, as they all depend on the number of stamina, without regard to any other circumstance: only it is to be observed that the 11th class, dodecandria, although its title is expressive of 12 stamina only, consists of such plants as are furnished with any number of stamina from 11 to 19 inclusive. The reason of the chasm in the classes from 10 to 12 stamina, is, that no flowers have yet been found with only 11, so as to form a class. The reseda indeed has sometimes 11, but often more; and those of the brownea are united below, which brings it under monadelphia.

The 12th class requires more attention. When the stamina amount to above 20, a young botanist will be apt to imagine that the plant belongs to the polyandria class. In reducing plants of this kind to their classes, particular regard must be had to the insertion of the stamina. If they are inserted into the calyx, the plant belongs to the icosandria class; if into the receptacle, it belongs to the polyandria. This distinction it is very necessary to observe, as the fruits of the latter class are frequently poisonous.

The 14th class is likewise in danger of being confounded with the 4th, the number of stamina being the same; but in the 14th, two of them are uniformly much shorter than the other two; at the same time each particular stamen belonging to the different pairs stands directly opposite to one another. The plants of this class are all labiate, or gaping blossoms, as in the snapdragon, foxglove, ground ivy, &c. The 15th class may be mistaken for the 6th, as they consist of the same number of stamina; but in the 15th, four of them are uniformly longer than the other two, and these two are always opposite to each other. The plants of this class are all cruciform; that is, four petalled, like a cross, as in the cabbage, wall flower, &c.

In the 16th class, the stamina are united below, but distinct above. The pistilla are also united below in one substance with the receptacle, which is prominent in the centre, but divided above into as many threads as there are germina.

In the 17th class, the corolla is papilionaceous, butterfly shaped, and the petals are expressed by distinct names; *viz.* vexillum, the uppermost, which covers the rest; alæ, the two at each side of the flower; and carina, the lowest, which is often bipartite, and placed between the alæ. The antheræ are most frequently 10, one on the upper filament, and nine on the lower. The pistillum grows out of the receptacle within the calyx. See the common pea.

The 19th class consists of plants whose flowers are composed of a great number of small flowers, enclosed in one common calyx, and therefore styled compound flowers. The whole compound flower in its aggregate state is styled flosculose, because composed of these flosculi or florets. The essence of a flosculose flower consists in having the antheræ united in a cylinder, and a single seed below the receptacle of the floret.

In the 20th class, the stamina grow either upon the pistillum, or upon a receptacle that stretches out in the form of a stylus, and supports both the stamina and the pistillum. The other classes are sufficiently distinguished in the table.

Sect. III. *Of the orders of plants.*

The orders are inferior divisions, which lead us a step nearer the genus. In the first 13 classes they are taken from the female parts, in the same manner as the classes from the male; and named monogynia, digynia, trigynia, tetragynia, &c. *i.e.* one, two, three, four, &c. pistilla, or female parts. When the pistils have no stalk or filament like the stamina, they are numbered by the stigmata or tops of the pistils, which in that case adhere to the capsule in the form of small protuberances, as may be observed in the flowers of the poppy, &c.

In the 14th class the orders are derived from a different source. The plants belonging to it have their seeds either enclosed in a capsule, or altogether uncovered. Hence they are divided into gymnospermia, comprehending such as have naked seeds; and angiospermia, comprehending such as have their seeds covered, or enclosed in a capsule.

The 15th class is divided into two orders, *viz.* the siliculosa, or those which have a short pod: and the siliquosa, or those which have a longer one.

The orders of the 16th, 17th, 18th, and 20th classes, are taken from the number of stamina; *e.g.* monadelphia pentandria, decandria, polyandria, &c.

The orders of the 19th class are, 1. polygamia æqualis, those whose floscules are all furnished with stamina and pistils. Polygamia spuria, comprehends plants that have hermaphrodite floscules in the disk, and female floscules in the margin; which is made the foundation of the three

next orders, *viz.* 2. Polygamia superflua, those whose hermaphrodite flowers in the disk are furnished with stigmata, and bear seed, and whose female flowers in the radius likewise produce seeds. 3. Polygamia frustranea, such as have hermaphrodite seedbearing floscules in the disk; but whose floscules in the radius, having no stigmata, are barren. 4. Polygamia necessaria, is the reverse of the former: the hermaphrodite flowers in the disk want stigmata, and are barren; but the female floscules in the radius are furnished with stigmata, and produce seeds. 5. Polygamia segregata, many floscules enclosed in one common calyx, and each of the floscules likewise furnished with a perianthium proper to itself. 6. Monogamia. This order consists only of seven genera, none of which have properly compound flowers, but are ranked under this class merely from having their stamina united by the antheræ.

The orders of the 21st class are partly taken from the number of stamina, and partly from the names and characters peculiar to some of the other classes; *e.g.* monoecia triandria, monoecia syngenesia, monoecia gynandria.

The orders of the 22d class are founded upon the number, union, and situation of the stamina in the male flowers. The orders of the 23d are all taken from classical characters; *e.g.* polygamia monoecia, polygamia dioecia, and polygamia trioecia.

The 24th class is divided into four orders: 1. Filices, comprehending all plants that bear their seeds in the back or edges of the leaf, and those that are called capillary plants. 2. Musci, which comprehends all the moss kind. 3. Algæ, including the lichens, fuci, and many others whose parts of fructification are either altogether invisible or exceedingly obscure. 4. Fungi, comprehending all the mushroom tribe.

For a delineation of the classes, &c. see Plates XX. and XXI.

TABLE OF THE ORDERS.

Classes.	Number and Names of the Orders.
1. Monandria	2 Monogynia, Digynia,
2. Diandria	3 Monogynia, Digynia, Trigynia.
3. Triandria	3 Monogynia, Digynia, Trigynia.
4. Tetrandria	3 Monogynia, Digynia, Tetragynia.
5. Pentandria	6 Monogynia, Digynia, Trigynia, Tetragynia, Pentagynia, Polygynia.
6. Hexandria	5 Monogynia, Digynia, Trigynia, Tetragynia, Polygynia.
7. Heptandria	4 Monogynia, Digynia, Tetragynia, Heptagynia.
8. Octandria	4 Monogynia, Digynia, Trigynia, Tetragynia.
9. Enneandria	3 Monogynia, Trigynia, Hexagynia.
10. Decandria	5 Monogynia, Digynia, Trigynia, Pentagynia, Decagynia.
11. Dodecandria	5 Monogynia, Digynia, Trigynia, Pentagynia, Dodecagynia.
12. Icosandria	5 Monogynia, Digynia, Trigynia, Pentagynia, Polygynia.
13. Polyandria	7 Monogynia, Digynia, Trigynia, Tetragynia, Pentagynia, Hexagynia, Polygynia.
14. Didynamia	2 Gymnospermia, Angiospermia.
15. Tetradynamia	2 Siliculosa, Siliquosa.
16. Monadelphia	8 Triandria, Pentandria, Octandria, Enneandria, Decandria, Endecandria, Dodecandria, Polyandria.
17. Diadelphia	4 Pentandria, Hexandria, Octandria, Decandria.
18. Polyadelphia	4 Pentandria, Dodecandria, Icosandria, Polyandria.
19. Syngenesia	6 Polygamia æqualis, Polygamia superflua, Polygamia frustranea, Polygamia necessaria, Polygamia segregata, Monogamia.
20. Gynandria	9 Diandria, Triandria, Tetrandria, Pentandria, Hexandria, Octandria, Decandria, Dodecandria, Polyandria.
21. Monoecia	11 Monandria, Diandria, Triandria, Tetrandria, Pentandria, Hexandria, Heptandria, Polyandria, Monadelphia, Syngenesia, Gynandria.
22. Dioecia	15 Monandria, Diandria, Triandria, Tetrandria, Pentandria, Hexandria, Octandria, Enneandria, Decandria, Dodecandria, Icosandria, Polyandria, Monadelphia, Syngenesia, Gynandria.
23. Polygamia	3 Monoecia, Dioecia, Trioecia.
24. Cryptogamia	4 Filices, Musci, Algæ, Fungi.
Appendix	1 Palmæ.

Some botanists rank these last as a 25th class; but this is improper, as they are all capable of being arranged in the preceding classes of the system, although on account of their singular structure, Linnæus placed them in an appendix. They contain such genera as have a spadix and spatha, *i.e.* whose flowers and fruit are produced on that particular receptacle called a spadix, protruded from a common calyx in form of a sheath, called spatha. This order consists of trees and shrubs only. These have always a simple stem, not branched, bearing leaves at the top, resembling those of fern, being a composition of a leaf and a branch, called frondes; and the corolla has always 3 petals. See Plates XX. and XXI. Botany.

Sect. IV. *The genera of plants.*

In investigating the genus of a plant, we must first consider its essence. The essence of every vegetable, says Linnæus, consists in the fructification; the essence of the

fructification in the flower and fruit; the essence of the flower consists in the antheræ and stigma, and the essence of the fruit in the seed. Hence he makes the flower and fruit the foundation of his generic distinctions.

These are generally composed of seven parts; the calyx, the corolla, the stamina, the pistillum, the pericarpium, the semina, and the receptaculum; and the presence or absence, the number, figure, proportion, and situation, of the several parts, constitute the genus. But as there are few genera wherein all the parts of the natural character are constant in every one of the species, it is necessary to fix upon such circumstances as are constant in both genus and species, and call those the essential or ruling character; both to distinguish one genus from another, and to fix the several species and their varieties to their respective genera; for which purpose, in some cases, Linnæus was obliged to have recourse to the nectarium. The first four parts of the fructification are properly parts of the flower, and the last three of the fruit.

I. The calyx, or cup, is the termination of the outer bark of a plant. Its chief use is to enclose, support, and protect, the other parts of the fructification. When present, it is seated on the receptacle: and is distinguished by its figure; by the number, division, and shape of its leaves, or segments; and by the following names, according to the circumstances with which it is attended.

1. Perianthium, when its station is close to, and surrounds, the other parts of the fructification, is called the perianthium of the fructification: if it includes many floscules, as in scabiosa, and other aggregate and compound flowers, it is called a common perianthium: if it includes only one floscule, it is called a proper perianthium; if it includes the stamina, and not the germen, it is the perianthium of the flower, and is said to be above, as in lonicera, ribes, campanula, &c. if it includes the germen, but not the stamina, it is the perianthium of the fruit, and is said to be below, as in linnea and morina, each of which have two calyxes and two receptacles above each other, one of the flower and the other of the fruit.

2. Involucrum, when stationed at the foot of an umbel, below the common receptacle, and at a distance from the flower, is called universal, if placed under the universal umbel; and partial, if placed under a partial umbel.

3. Amentum, consists of a great number of chaffy scales, disposed along a slender axis or common receptacle, which, from its resemblance to a cat's tail, has obtained the name of catkin; and these flowers have generally no petals: sometimes the same amentum supports both male and female flowers, distinct, on the same plant, as in carpinus, &c. sometimes the male and female flowers are removed from each other on the same plant, and the amentum supports only the male flowers, and the female flowers are enclosed by a perianthium, as in corylus, fagus, &c. and sometimes an amentum only supports male flowers on one plant, and female flowers on another plant, as in salix, populus, &c.

4. Spatha, a sort of calyx growing from the stalk, bursting lengthwise, and protruding a spadix, supporting one or more flowers, which have often no perianthium. It consists either of one leaf, with a valve on one side only, as in the greater number of spathaceous plants; or of two leaves, with two valves, as in stratiotes, &c. or is imbricated, as in musa, &c. with one or two valves.

5. Gluma, a husk, chiefly belongs to corn and grasses, consisting of one, two, three, or more valves, folding over each other like scales, and frequently terminated by a long, stiff, pointed prickle, called the arista.

6. Calyptra, the proper calyx of mosses, is placed over the antheræ of the stamina, resembling an extinguisher, a hood, or monk's cowl.

7. Volva, so named from its infolding, is the proper calyx of funguses, being membranaceous, and surrounding the stalk, before their expansion.

It is often difficult to distinguish the calyx from the bracteæ, which are found on many plants, situated on the flower stalks: and are often so near to the lower parts of the fructification as to be mistaken for the calyx, as in tilia, passiflora, &c. but they may be best distinguished by this rule; the bracteæ differ in shape and colour from the other leaves of the plant, but are commonly of the same duration; whereas the calyx always withers when the fruit is ripe, if not before.

II. The corolla is the termination of the inner bark of the plant; which accompanies the fructification, in the form of leaves variously coloured. It is generally seated on the receptacle, sometimes on the calyx; serving as an inner work of defence to the part it encloses; as the calyx, which is usually of stronger texture, does for an outer. The leaves of the corolla are called petals; by the number, division, and shape of which, it is distinguished. It is said to be inferior or below, when it includes the germen, and is attached to the part immediately below it, as in borago, &c. and it is said to be superior or above, when it is placed above the germen, as in cratægus, &c. In respect to duration, the corolla either continues till the fruit is ripe, as in nymphæa; or falls off at the first opening of the flower, as in actæa; or with the stamina and other parts of the flower, as in most plants; or does not fall, but withers, as in campanula, &c.

The nectarium, Linnæus says, principally belongs to the corolla, as an appendage to the petals; and contains the honey, which is the principal food of bees and other insects. But though, in plants where it is found, it may be attached to the corolla, and be then most evident; yet it is almost as often attached to other parts of the fructification: Linnæus therefore chiefly makes use of it as an essential character in many of the genera, as being less variable than others; and observes, that when it is not united with the substance of the petals, those plants are generally poisonous; the tube or lower part of monopetalous flowers, he considers as a true nectarium, because it contains a sweet liquor. But as it affords very singular varieties in other instances, it has the following distinctions.

1. Calycine nectaria, such as are situated upon, and make a part of, the calyx; as in tropæolum, monotropa, &c.

2. Corollaceous nectaria are attached to the corolla, and are called calcariate when they resemble a spur. They are either on flowers of one petal, as in valeriana, &c. or on flowers of many petals, as in viola, &c. or within the substance of the petals, as in lilium, iris, &c.

3. Stamineous nectaria attend the stamina, and are either seated upon the antheræ, as in adenanthera; or upon the filaments, as in laurus, &c.

4. Pistillaceous nectaria accompany the pistillum, and are placed upon the germen, as in hyacinthus, butomus, &c.

5. Receptaculaceous nectaria join the receptacle, as in polygonum, sedum, &c.

6. Nectaria that crown the corolla, are placed in a row within the petals, though entirely unconnected with their substance, as in silene, &c. and in this situation often resemble a cup, as in narcissus, &c.

7. Nectaria of singular construction, are such as cannot properly be placed under any of the foregoing distinctions, as in amomum, curcuva, saliva, urtica, &c. The proper use of the nectarium is not yet discovered.

III. The stamina, or chives, are the males of the flower, proceeding from the wood of the plant. Each stamen consists of two parts, *viz.* the filament and the antheræ. In most flowers they are placed upon the receptacle, within the corolla, and round the germen; and are chiefly distinguished by number.

1. The filament is the thread shaped part of the stamen, serving as a footstalk to elevate the antheræ, and sometimes has jags or divisions; which are either two, as in salvia; three, as in fumaria; or nine, as in the class diadelphia. They are also distinguished by their form or figure, as awl shaped, thread shaped, hair like, spiral, revolute, &c. by their proportion, as equal, unequal, irregular, long, or short: and by their situation, being generally opposite to the leaves or divisions of the calyx, and alternate with the petals; that is, when the divisions of the calyx are equal in number to the petals, and to the stamina. In monopetalous flowers they are generally inserted into the corolla; but scarcely ever in flowers of more than one petal, but into the receptacle; yet in the class icosandria they are inserted into the calyx or corolla, though the flowers have many petals, as also in a few other plants. But in the class polyandria, and most other polypetalous plants, they are inserted into the receptacle, like the calyx and corolla. The class gynandria, however, is an exception to the above rules, where the stamina are sometimes without filaments.

2. The anthera, from ανθος, a flower, emphatically so called from its great utility in the fructification, is the top of the filament, containing the impregnating pollen; and is either one to each filament, as in most plants; or one common to three filaments, as in cucurbita, &c. or one common to five filaments, as in the class syngenesia: or sometimes there are two antheræ to each filament, as in ranunculus and mercurialis; three to each filament, as in fumaria; five to three filaments, as in bryonia; or five to each, as in theobroma. The anthera is also distinguished by its form or figure, as oblong, round, angular, &c. It consists of one or more cells, which burst differently in different parts; either in the side, as in most plants; on the top; or from the top to the base. It is also fastened to the top of the filament; either by its base, as in most plants; or horizontally by its middle to the top of the filament, so poised as to turn like a vane: or it is fixed by its side, leaning to the top of the filament, then called incumbent. Sometimes it grows to the nectarium, as in costus; to the receptacle, as in arum; or to the pistillum, in the class gynandria.

IV. The pistillum, or the female of the flower, proceeding from the pith of the plant, is that erect column which is generally placed in the centre of the flower, amidst the stamina; and consists of three parts, the germen, the style, and the stigma.

1. The germen is the base of the pistillum, supporting the style. After some time, it becomes a seed vessel, and may therefore be considered as the rudiment of the pericarpium. It is distinguished by its shape, number, and situation; and is said to be above or below, according to its situation above or below the attachment of the corolla.

2. The style elevates the stigma from the germen, to receive the influence of the stamina, and to convey it down to the germen as through a tube. It is distinguished either by its number, which, when present (or when absent, the number of stigmata) gives rise to most of the orders, and are called so many females; or by its divisions, being double, treble, or quadruple, &c. though joined at the base; or by its length, being longer, shorter, or equal with the stamina; or by its proportion, being thicker or thinner than the stamina; or by its figure, being regular, cylindric, awl shaped, bent, &c. or by its situation, being generally on the top of the germen, though in some instances supposed to be both above and below, as in capparis and euphorbia; unless the lower part in these genera are considered as the extension of the receptacle. It is often placed on the side of the germen, as in hirtella, suriana; also in rosa, rubus, and the rest of the plants in the class icosandria and order polygynia. With respect to duration, it generally falls with the other parts of the flower; but in some plants it is permanent, and attends the fruit to its maturity, as in the class tetradynamia. In flowers which have no style, the stigma adheres to the germen.

3. The stigma, when single, is generally placed like a head on the summit of the style: when several, they are placed on the top, or regularly disposed along the side; and covered with moisture, to retain the pollen of the antheræ. It is distinguished either by its number, being single in most plants; or by its divisions, figure, length, thickness, or duration; as in most plants it withers when the germen is become a seed vessel; in some it is permanent, as in papaver.

V. The pericarpium is the germen grown to maturity, and become a matrix. All plants, however, are not furnished with a seed vessel, as corylus, &c. In many, it is supplied chiefly by the calyx, which converging encloses the seeds till they arrive at maturity; as is the case with the rough leaved plants, and the labial and compound flowers of the classes pentandria, didynamia, and syngenesia. Sometimes the receptacle supplies the office of seed vessel, as in gundelia; and sometimes the nectarium, as in carex. The pericarpium is situated at the receptacle of the flower, either above or below, or both, as in saxifraga and lobelia: and is distinguished by the following appellations, according to its different structure.

1. Capsula is frequently succulent whilst green; but when ripe, it is a dry husky seed vessel, that parts to discharge its contents: and by some elastic motion, the seeds are often darted forth with considerable velocity, as in dictamnus, &c. It opens either at the top, as in most plants; at the bottom; at the side, horizontally across the middle; or longitudinally; and if it is articulated or jointed, it opens at each of the joints, which contains a single seed. It is distinguished externally, by its number of valves; and internally, by the number of its cells, wherein the seed is enclosed; as well as by its shape and substance.

2. Siliqua, a pod, is a pericarpium of two valves; but as some are long, others round or broad, Linnæus

distinguishes them by their form into siliqua and silicula, which give name to the two orders in the class tetradynamia. The siliqua is a long pod, being much longer than broad, as in brassica, sinapis, &c. the silicula, a little pod, is a roundish pod, either flat or spherical, and the length and breadth nearly equal, as in lunaria, draba, &c. In both, the apex, which had been the style, is often so long beyond the valves, as to be of equal length with the pod; and the seeds in both are fastened alternately by a slender thread, to both the sutures or joinings of the valves.

3. Legumen, pulse, is also a pod, and is likewise a pericarpium of two valves, wherein the seeds are fastened to short receptacles along the upper suture only, on each side, alternate: this chiefly belongs to the papilionaceous flowers, or the class diadelphia.

4. Folliculus, or conceptaculum, is a pericarpium of one valve only, opening lengthwise on one side, and the seeds not fastened to the suture, but to a receptacle within the fruit, as in asclepias, &c.

5. Drupa is a pericarpium that is pulpy, having no valve. It contains within its substance a nut, or seed enclosed with a hard ligneous crust, as olea, cornus, &c. and when the drupa is seated below the calyx, it is furnished with an umbilicus like the pomum.

6. Pomum, an apple, is also a pulpy pericarpium without a valve; but containing in the middle a membranous capsule, with several cells containing the seeds; and at the end opposite to the footstalk there is generally a small cavity, called umbilicus from its resemblance to the navel in animals; and which was formerly the calyx, seated above the fruit, and persistent, as in pyrus, cucumis, &c.

7. Bacca, a berry, is also a pulpy pericarpium without valve, enclosing one or more seeds, which have no membranous capsule or covering, but are disposed promiscuously through the pulp, as in solanum, &c. and are generally placed on footstalks attached to receptacles within the pulp, as in ribes, &c. The berry also admits of the following distinction: it is said to be proper, when it is a true pericarpium formed of a germen; and improper, when it is formed from other parts of the fructification, as in rosa, juniperus, &c. A large succulent calyx becomes a berry; and in juniperus, the three petals become the umbilicus; in poterium the berry is formed of the tube of the corolla; in fragraria, &c. it is formed of the top of the receptacle; in rubus, &c. it is formed from a seed, which is the receptacle of the berry; in ruscus, &c. it is enclosed within and is a part of the nectary. The berry is commonly either round or oval, and is frequently furnished with an umbilicus, as in ribes, &c. it does not naturally open to disperse the seeds like the capsule, that office being performed by birds and other animals.

8. Strobilus is a pericarpium formed of an amentum, being a seed vessel composed of woody scales placed against each other in the form of a cone, opening only at the top of the scales, being firmly fixed below to a sort of axis or receptacle, occupying the middle of the cone; as in pinus, &c. For parts of flowers and fruits, see Plates III and V. Botany.

VI. Semina, the seeds, are the essence of the fruit of every vegetable, and defined by Linnæus to be "a deciduous part of the plant, containing the rudiments of a new vegetable, fertilized by the sprinkling of the pollen." They are distinguished according to number, shape, texture, appendage, &c. A seed, properly so called, consists of the five following parts; to which are added the nux and propago.

1. The corculum, from cor, a heart, is the essence of the seed, and principle of the future plant; and consists of two parts, *viz.* plumula and rostellum. The plumula is the part which shoots up into the stem, and the rostellum is what forms the root. See Physiology of Plants.

2. The cotyledons, from cotyledon, the hollow of the huckle bone, are the thick porous side lobes of the seed, such as the two sides into which a bean divides when soaked in water, and which afterward come up as the seed leaves of the plant. If a plant is cut below the cotyledons, it will scarcely ever put out fresh leaves, but withers and decays; if it is cut above the cotyledons, it generally shoots out afresh, and continues to grow: therefore, if plants whose cotyledons rise above ground, as turnips, &c. are cut or eaten into the ground by cattle, they decay; but where the cotyledons remain below ground, as in grasses, and are cut or eaten to the ground, they will shoot out afresh. Some plants have only one, as in grasses and in cuscuta, &c. others two, as in vicia, &c. linum has four; cupressus, five; and pinus, ten.

3. The hilum, the black spot on a bean, called the eye, is the external mark on the seed, where it was fastened within the pericarpium.

4. The arillus, the proper exterior coat of the seed, that falls off spontaneously, is either cartilaginous or succulent: yet seeds are said to be naked, when not enclosed in any sort of pericarpium, as in the class and order didynamia gymnospermia.

5. The coronula is either a small sort of calyx adhering to the top of the seed, like a little crown, and assisting to disperse it by flying, as in scabiosa, knautia, &c. where the little calyx of the floret becomes the crown of the seed: or a down, which is either feathery, as in valeriana, &c. or hairy, as in tussilago, &c. This down has generally been thought intended to disperse the seed. The coronula is either also sitting, that is, attached close to the seed, as in hieracium, &c. or footstalked by a thread elevating and connecting the tuft with the seed, as in crepis, &c. Some seeds are furnished with a wing, a tail, a hook, an awn, &c. all coming under the term coronula, and tending either to disperse or fix the seeds. Some have an elastic force, to disperse them; which is either in the calyx, as in oats and some others; in the pappus, as in centurea crupina; or in the capsule, as in geranium, &c. Other seeds, especially those whose pericarpium is a berry, as also the nutmeg and other nuts, are dispersed by birds and other animals.

Nux, a nut, a seed enclosed in a hard woody substance, called the shell, which is one celled, two celled, &c. and the enclosed seed is called the kernel.

Propago, a slip or shoot, the seed of a moss, which has neither coat nor cotyledon, but consists only of a naked plumula, where the rostellum is inserted into the calyx of the plant.

VII. The receptaculum is the base which receives, supports, and connects, the other parts of the fructification. It is only mentioned by Linnæus, when it can be introduced as a character varying in shape and surface, as princi-

pally in the class syngenesia. It is called proper when it supports the parts of a single fructification only; when it is a base to which only the parts of the flower are joined, and not the germen, it is called a receptacle of the flower; in which case the germen, being placed below the receptacle of the flower, has a proper base of its own, which is called the receptacle of the fruit: and it is called a receptacle of the seeds, when it is a base to which the seeds are fastened within the pericarpium. In some simple flowers, where the germen is placed above the receptacle of the flower, the fruit has a separate receptacle, as in magnolia, uvaria, &c. in which genera the numerous germina are seated upon a receptacle rising like a pillar above the receptacle of the fructification. It is styled common, when it supports and connects a head of flowers in common; as in the amentum, and other aggregate flowers. The umbella and cyma are also called receptacles. Rachis, a filiform receptacle, collecting the florets longitudinally into a spike, in many of the glumose flowers, as wheat, barley, rye, &c. Spadix anciently only signified the receptacle of a palm issuing out of a spatha, and branched; but now every flower stalk that is protruded from a calyx called spatha, is denominated a spadix, as in narcissus, &c.

Sect. V. *The species of plants.*

The genera include a great number of species, distinguished by the specific difference of the root, the trunk, the branches, the leaves, &c. yet all agreeing in the essential generic character. They are called by trivial names, expressive of the difference of some other circumstance, added to the generic name. To investigate the species, therefore, it is necessary to understand those differences, and to be acquainted with the names by which they are expressed. Several of these have been already incidentally explained; but for a complete enumeration, the reader must have recourse to the glossary.

In general it may be observed, that specific differences take their rise from any circumstance, wherein plants of the same genus disagree; provided such circumstance is constant, and not liable to alteration by culture or other accidents. Hence Linnæus asserts the species to be as numerous as there were different forms of vegetables produced at the creation; and considers all casual differences as varieties of the same species.

Hybrid, or mule plants, must be ranked among varieties, whether occasioned by accident, by the pollen of one plant falling upon the pistilla of another, or reared by art; of which Linnæus gives many curious instances.

Varieties may generally be reduced under their species, by comparing the variable marks of the variety with the natural plant; but there are some which are attended with difficulty, and require judgment and experience; particularly in some species of helleborus, gentiana, fumaria, valeriana, scorpiurus, and medicago. In these two last there is a remarkable diversity in the fruit of the individuals. In the medicago, or snail trefoil, in particular, the forms of the real snails, which nature has imitated in these plants, are scarcely more diversified than the fruit of this mimic species: so that the botanist who is studious of varieties, would find no end to his labour, were he to attempt to pursue nature through the various shapes she has wantonly adopted. The whole order of the fungi too, as Mr. Lee observes, is still a chaos; botanists not being yet able in these to decide what is a species, and what a variety.

Sect. VI. *Of the natural classes or orders.*

Notwithstanding the evident superiority of the sexual system, Linnæus and most other modern botanists are of opinion, that there is a natural method, or nature's system, which we should diligently endeavour to find out. On these principles, Linnæus divides vegetables into 58 natural classes or orders, *viz.*

1. Palmæ. These are perennial, and mostly trees or shrubs: such as the phœnix, or date palm, the cocos or cocoa nut tree, &c. They are astringent.

2. Piperitæ, peppers, are mostly herbaceous and perennial: such as the pothos, the stalks of which creep along rocks and trees, into which they strike root at certain distances; the arums, &c.

3. Calamariæ, reeds.

4. Gramina, grasses.

5. Tripetaloideæ have no very striking characters, but are nearly allied to the grasses. Such are the butomus, or water gladiole, &c.

6. Ensatæ, swordlike plants; as the saffron, iris, &c.

7. Orchideæ. The orchis kind.

8. Scitamineæ are beautiful exotics, all natives of very warm countries. Some of them furnish exquisite fruits: the amomum or ginger, and the musa or plantain, are included in this order. The roots are hot and resinous.

9. Spathaceæ are nearly allied in habit and structure to the liliaceous plants, from which they are chiefly distinguished by the spatha, out of which their flowers are protruded: such are the allium, the amaryllis, &c.

10. Coronariæ are herbaceous, perennial, and from one inch to 15 feet high. The roots are either bulbous, fibrous, or composed of small fleshy knots, jointed at top. The hyacinths and lilies belong to this tribe.

11. Sarmentosæ, from sarmentum, a long shoot, have climbing stems and branches, that, like the vine, attach themselves to other bodies for support: such are smilax, trillium, &c.

12. Holeraceæ, from holus a pot herb, contains trees, shrubs, perennial and annual herbs, chiefly for domestic use: such as the beet, rhubarb, &c.

13. Succulentæ. This order consists of flat, fleshy, and juicy plants, most of them evergreens. They are astringent, refreshing, and very wholesome.

14. Gruinales, cranelike, consist of geranium, and a few other genera which Linnæus considers as allied to it in their habit and external structure.

15. Inundatæ are aquatic plants, low, herbaceous, and mostly perennial. The elatine, hippuris, the pond weed, &c. are of this class. These plants are astringent.

16. Calycifloræ have the stamina inserted into the calyx, and are all of the shrub or tree kind: such is the elæagnus or wild olive, &c.

17. Calycanthemiæ have the corolla and stamina inserted into the calyx. Such are the epilobium, lythrum, willow herbs, &c. These plants are astringent.

18. Bicornes, plants whose antheræ have the appearance of two horns. Of these are the heaths, vacciniums, &c. These are also astringent.

19. Hesperideæ are of the shrub and tree kind, and mostly evergreen. Such as the myrtle, clove tree, &c.

20. Rotaceæ consist of plants with one wheel shaped petal without a tube; as the phlox, the cistus, hypericum, &c.

21. Preciæ, from precius, early, consist of primrose, an early flowering plant, and some others which agree with it in habit and structure.

22. Caryophylleæ, those which resemble the pink and carnation, including those plants, &c.

23. Trihilatæ consist of plants with three seeds, which are marked with an external cicatrix, where they are fastened within to the fruit. The acer, æsculus, &c. belong to this class.

24. Corydales have irregular flowers, somewhat resembling a helmet. Such are the impatiens or balsam, fumaria, &c.

25. Putamineæ, shelled, consist of a few genera of plants allied in habit, whose fruit is covered with a hard woody shell. The caper shrub and some other exotics are included in this class.

26. Multisiliquæ consist of plants which have more seed vessels than one. Such are the columbines, delphiniums, &c. They are caustic and purgative.

27. Rhæadeæ consist of poppy, and a few genera which resemble it in habit and structure. Upon being cut, they emit plentifully a juice which is white in poppy, and yellow in the others. These plants are narcotic.

28. Luridæ are an order of plants whose pale appearance indicates their baleful and noxious qualities. The atropa, datura, &c.

29. Campanaceæ have bell shaped flowers, including the convolvulus, &c. The plants are medicinal, and abound with a white milky juice.

30. Contortæ, plants which have a single petal twisted toward one side. The apocynum, asclepias, and even the periwinkle, are included in this class. The plants being cut, emit a juice, either of a milky or greenish white, which is deemed poisonous.

31. Vepreculæ, from vepres, a briar, consist of plants resembling the daphne, &c. but which do not constitute a true natural class.

32. Papilionaceæ, plants that have papilionaceous flowers, such as the common and sweet pea, &c. These plants are emollient.

33. Lomentaceæ, from lomentum, a colour used by painters, furnish beautiful tinctures, and some of them are much used in dyeing. The sophora, abrus, and supina, are found in this class. These plants are mucilaginous.

34. Cucurbitaceæ, from cucurbita, a gourd, plants which resemble the gourd in external figure, habit, virtues, and sensible qualities. Among these are the cucumber and melon. These plants are purgative.

35. Senticosæ, from sentis, a briar, consist of the rose, bramble, and other plants which resemble them in external structure. The fruits are cooling.

36. Pomaceæ, consist of plants which have a pulpy esculent fruit, of the apple, berry, or cherry kind.

37. Columniferæ, from columna, a pillar, and fero, to bear, plants whose stamina and pistil have the appearance of a pillar in the centre of the flower. Among these are the althea, camellia, tea tree, &c. The plants are mucilaginous and lubricating.

38. Tricoccæ, from τρεις, three, and κοκκος, a grain; plants with a single three cornered capsule, having three cells, each containing a single seed. Among which are box, phyllanthus, &c.

39. Siliquosæ, plants which have a pod for their seed vessel. Among these are the cabbage, mustard, &c. The plants are diuretic and antiscorbutic.

40. Personatæ, from persona, a mask, plants whose flowers are furnished with an irregular, gaping, or grinning petal, in figure somewhat resembling the snout of an animal. Such are the snapdragon, justicia, &c. The internal use of many of them is extremely pernicious; applied externally, they are anodyne, and powerful resolvents.

41. Asperifoliæ, rough leafed plants; as borage, bugloss, &c. They are diuretic and cordial.

42. Verticillatæ consist of herbaceous vegetables, having four naked seeds, and the flowers placed in whorls round the stalk; hyssop, lavender, dead nettle, &c. The leaves are cordial and cephalic.

43. Dumosæ, from dumus, a bush, are all of the shrub and tree kind, thick and bushy, rising from 6 to 25, 30, and even 40 feet high; elder, buckthorn, &c. The berries are purgative.

44. Sepiariæ, from sepes, a hedge, from their size, elegance, and other circumstances, are very proper for hedges. Ash, privet, lilac, &c.

45. Umbellatæ, plants whose flowers grow in umbels, with five petals that are often unequal, and two naked seeds joined at top and separated below. Parsley, æthusa, caraway, fennel, &c. furnish specimens of this tribe. The plants of this order, which grow in dry places, are sudorific, stomachic, and warming.

46. Hederaceæ, from hedera, ivy; consist of both herbaceous and shrubby plants, most of which, particularly ivy and vine, have creeping branches, which attach themselves by roots or tendrils to other bodies.

47. Stellatæ, from stella, a star, consist of plants with two naked seeds, and leaves disposed round the stem in form of a radiant star. Spigelia, dogwood, &c. belong to this order. They are opening and cordial.

48. Aggregatæ, plants which have aggregate flowers, consist of a number of florets, each of which have a proper and common calyx: as dipsacus, scabius, &c.

49. Compositæ, plants with compound flowers. Carduus, xeranthemum, &c. are of this tribe.

50. Amentaceæ, plants bearing catkins: salix, &c.

51. Coniferæ, from conus, a cone, and fero, to bear; plants whose female flowers, placed at a distance from the male, either on the same or distinct roots, are formed into a cone. The fir, pine, cypress, &c. all rank under this order. They are gummy and odorous.

52. Coadunatæ, from coadunare, to join, are so termed from the general appearance of the seed vessels, which are numerous, and being slightly attached below, form all together a single fruit in the shape of a sphere or cone; the parts of which, however, are easily separated. Such are the magnolia, tulip tree, &c.

53. Scabridæ, from scaber, rough, consist of plants with rough leaves, which seem to be akin to the asperifoliæ; only their degree of roughness is much greater. Hemp, fig, &c. They are astringent. Their taste is bitter and styptic.

54. Miscellaneæ, miscellaneous plants. This order consists of such genera as are not connected together by very numerous relations.

55. Filices, ferns, bear their flower and fruit on the back of the leaf or stalk. They are opening and attenuating.

56. Musci, mosses, resembling the pines, firs, and other evergreens of that class, in the form and disposition of their leaves, and manner of growth of the female flowers, which are generally formed into a cone. They frequently creep, and extend like a carpet upon the ground, trees, and stones; being generally collected into bunches and tufts; the smallest are only one third of an inch in height, and the largest do not exceed five or six.

57. Algæ, flags, or rather sea weeds, consist of marine plants, &c. whose root, leaf, and stem, are all one.

58. Fungi, mushrooms, are rarely branched, sometimes creeping, but most commonly erect. These plants are very astringent. As food, they are at best suspicious; some of them are rank poison.

Plantæ dubii ordinis, plants of uncertain order. Under this name Linnæus classes all the other genera which cannot be reduced to any of the above mentioned orders, and which are near 129 in number.

Though we have already explained the most essential botanical terms, yet the student will often find it advantageous to have recourse to the following glossary; which we would even recommend, should he in any of our descriptions of genera find a term which he does not understand.

A.

Abbreviatum perianthium, a shortened cup, when the cup is shorter than the tube of the flower.
Abortiens flos, a barren flower, such as produces no fruit.
Abrupta folia pinnata, winged leaves, ending without either foliole or cirrhus.
Acaulis, without stalk or stem.
Acerosa folia, chaffy leaves, when they are linear and abiding.
Acicularis, needle shaped.
Acinaciform, falchion or cimeter shaped.
Acini, the small berries of a mulberry or bramble.
Acotyledones, plants whose seeds have no cotyledons or seminal leaves.
Aculei, prickles, fixed in the surface of the bark.
Aculeatus caulis, a stalk or stem furnished with prickles.
Acuminatum folium, a leaf ending in a point.
Acutum folium, a leaf terminating in an acute angle.
Adnatum folium, the disk of the leaf pressing close to the stem of the plant.
Adpressum folium, the disk of the leaf pressed to the stem.
Adscendens caulis, or ramus, a stalk or branch inclining upward.
Adversum folium, an opposite leaf.
Alæ, wings, the side petals of a papilionaceous blossom, or membranes added to a seed, stalk, &c.
Alated, winged.
Alatus petiolus, the footstalk of a leaf winged with membranes.
Alburnum, the white substance that lies between the inner bark and the wood of trees.
Alterni rami folia, leaves that come out singly, and follow alternately in gradual order.
Alveolated, deeply pitted, resembling a honeycomb.
Amentum, a thong, or a catkin.
Amplexicaule folium, a leaf embracing the stalk, when the base of the leaf embraces the stem sideways.
Anceps caulis, a double edged stalk, *i.e.* compressed and forming two opposite acute angles.
Ancipitous, two edged.
Angulatus caulis, an angulated stalk.
Angustifolious, narrow leaved.
Angiospermia, plants whose seeds are covered with a capsule.
Annua radix, an annual root; that which lives but one year.
Anthera, the summit of the stamen.
Apertura, an opening in some species of antheræ.
Apetalous, having no petals or corolla.
Apex, the top or summit.
Aphyllous, destitute of leaves.
Apophysis, an excrescence from the receptacle of the musci.
Appendiculatus petiolus, a little appendage hanging from the extremity of the footstalk.
Appressed, approaching to the stem.
Approximata folia, leaves growing near each other.
Arbor, a tree.
Arboreus, arborescent; of the nature of a tree; producing buds.
Arbustiva, a copse of shrubs or trees.
Arcuatum legumen, a curved or bent pod.
Arista, the beard of corn or grasses.
Articulatus caulis, a stem with knots or joints.
Articulus culmi, the straight part of the stalk between the two joints.
Assurgentia folia, leaves first bent down, but rising erect toward the apex.
Attenuatus pedunculus, a footstalk that grows smaller toward the flower.
Auctus calyx, an augmented flower cup, having a series of distinct leaves, shorter than its own, that surround its base.
Avenia folia, leaves which have no visible veins.
Auriculatum folium, an ear shaped leaf, when the leaf toward the base has a lobe on each side.
Axillaria folia, leaves growing out of the angles formed by the branches and the stem.

B.

Barba, a beard, a species of pubescence, sometimes on the leaves of plants.
Barbata folia, leaves terminated by a bunch of strong hairs.
Bicapsular, having two capsules.
Biennis radix, a biennial root, which continues to vegetate two years.
Bifaria folia, leaves pointing two ways.
Biferæ plantæ, leaves that flower twice a year.
Bifidum folium, a leaf divided into two parts.
Biflorus pedunculus, a footstalk bearing two flowers.
Bigeminum folium, a forked footstalk, with two little leaves on the apex of each division.
Bijugum folium, a winged leaf bearing two pair of foliola.
Bilabiata corolla, a corolla with two lips.
Bilobatum folium, a leaf consisting of two lobes.
Binatum folium, a digitate leaf, consisting of two foliola.
Bipartitum folium, a leaf divided into two segments.

Bipinnatum folium, a double winged leaf, when the folioles of a pinnate leaf are also pinnate.
Biternatum folium, a leaf where there are three folioles on a petiole, and each foliole is ternate.
Bivalve, consisting of two valves.
Brachiatus caulis, a stem branching in pairs, each pair standing at right angles with those above and below.
Brachium, the arm, the tenth degree in the Linnæan scale for measuring plants, being 24 Parisian inches.
Bracteatus, having a bractea growing out of it.
Bulbiferus caulis, a stalk bearing bulbs, as in lilium bulbiferum.
Bulbosa radix, a bulbous root.
Bullatum folium, a leaf whose surface rises above the veins, so as to appear like blisters.

C.

Caducus calyx, a flower cup that falls off at the first opening of the flower.
Calcariatus, resembling a spur.
Calyculatus calyx, a little calyx added to a larger one.
Calyptra, a veil or covering.
Campanulata corolla, a bell shaped flower.
Canaliculata folia, leaves having a deep channel running from the base to the apex.
Capillaceum folium, a capillary eaf.
Capillaris pappus, hairy down.
Capillus, hair, the first degree of the Linnæan scale for measuring plants; the diameter of the hair, and the 12th part of a line.
Capitati flores, flowers collected into heads.
Capitulum, a little head; a species of inflorescence, in which the flowers are connected into close heads on the tops of the peduncles, as in gomphrena.
Capreolus, a tendril.
Capsula, a little chest or capsule.
Carina, a keel, the lower petal of the papilionaceous corolla.
Carinatum folium, a leaf whose beak resembles the keel of a ship.
Carnosum folium, a fleshy leaf.
Cartilagineum folium, a leaf whose brim is furnished with a margin of different substance from the disk.
Caryophyllæus flos, a flower growing like a carnation.
Catenulata scabrities, a species of glandular roughness, hardly visible, resembling little chains, on the surface of some plants.
Caudex, the stem of a tree.
Caulescens, having a stalk or stem.
Caulina folia, leaves growing immediately on the stem.
Caulis, a stem, a species of trunk.
Cernuus, nodding or hanging down the head.
Cespitosæ, plants which produce many stems from one root, and form a surface of turf or sod.
Ciliatum, ciliated, with the margin guarded by parallel bristles, formed like the eyelash.
Circinalea folia, leaves within the bud, rolled spirally downward.
Circumscissa capsula, a capsule cut transversely.
Cirrhiferus pedunculus, a peduncle bearing a tendril.
Cirrhosum folium, a leaf that terminates in a tendril.
Cirrhus, a clasper, or tendril.
Classis, a class; defined by Linnæus to be an agreement of several genera in the parts of fructification, according to the principles of nature distinguished by art.
Clavatus petiolus, or pedunculus, a footstalk with the leaf or flower club shaped, tapering from the base to its apex.
Clavicula, a little key or tendril.
Clausa corolla, a corolla with its neck close shut in with valves.
Coarctati rami, branches close together.
Cochleatum legumen, a pod like the shell of a snail, as in medicago.
Coloratum folium, a leaf of any colour different from green.
Columnella, a little column, the substance that passes through the capsule, and connects the several partitions and seeds.
Columniferæ, pillar shaped.
Coma, a bush; a species of fulcrum composed of large bracteæ, which terminate the stalk.
Communis gemma, the common contents of the bud, both flower and fruit.
Communis calyx, a common flower cup containing both receptacle and flower.
Comosa radix, a bulbous root with fibres resembling hair.
Compactum folium, a leaf of a compact and solid substance.
Completus flos, a complete flower, having a perianthium and corolla.
Compositus caulis, a compound stem, diminishing as it ascends.
Compositum folium, a compound leaf, when the petiole bears more than one leaf.
Compressum folium, a leaf resembling a cylinder compressed on the opposite sides.
Concavum folium, a hollowed leaf, the margin forming an arch with the disk.
Conceptaculum, a receiver.
Conduplicatum folium, a leaf doubled together, when the sides are parallel and approach.
Conferti rami, branches crowded together.
Confertus verticillus, a species of inflorescence, wherein flowers and leaves are crowded, and formed into whorls round the stalk.
Confluentia folia, leaves flowing together, as in the pinnated leaf, when the pinnæ run into one another.
Conglobatus flos, a flower collected into a globular head.
Conglomerati flores, flowers irregularly crowded together.
Congesta umbella, flowers collected into a spherical shape.
Conica scabrities, a species of cetaceous scabrities, formed like cones, scarce visible, on the surface of plants.
Coniferæ, plants bearing cones.
Conjugatum folium, a pinnated leaf, where the folioles come by pairs.
Connata folia, two opposite leaves united at their base, so as to have the appearance of one leaf.
Connivens corolla, a corolla wherein the apices of the petals converge so as to close the flower.
Conniventes antheræ, antheræ approaching together.
Continuatum folium, a continued leaf, or one which appears to be a continuation of the substance of the stalk.
Contrariæ valvulæ, contrary valves, *i.e.* when the dissepimentum is placed transversely between them.
Convexum folium, a leaf rising from the margin to the centre of the leaf.

Convolutus cirrhus, a tendril twining in the same direction with the sun's motion.
Convolutum folium, a leaf rolled up like a scroll.
Cordatum folium, a heart shaped leaf.
Cordiformis, shaped like a heart.
Corolla, a wreath or little crown.
Corollula, a little corolla.
Corona seminis, a crown adhering to many kinds of seeds, serving them as wings, which enables them to disperse.
Cortex, the outer rind or bark.
Crenatum folium, a notched leaf.
Crispum folium, a curled leaf, when the circumference becomes larger than the disk admits of.
Cristatus flos, a flower with a tufted crest.
Cruciated flowers, } cross shaped flowers, consisting of
Cruciformes flores, } four petals disposed in the form of a cross.
Cubitus, a cubit, the 9th degree of the Linnæan scale for measuring plants, from the elbow to the extremity of the middle finger, or 17 Parisian inches.
Cucullata folia, leaves rolled up lengthwise in the form of a cone.
Culmen, the top or crown of any thing.
Culmus, a reed or straw, the stem of a grass.
Cuneiforme folium, a wedge shaped leaf.
Cuspidatum folium, a leaf whose apex resembles the point of a spear.
Cyathiformis corolla, a flower in the form of a cup.
Cylindracea spica, a spike in the form of a cylinder.
Cymbiform, keel shaped.

D.

Dædaleum folium, a leaf whose texture is remarkably beautiful.
Debilis caulis, a weak feeble stalk.
Decaphyllous calyx, a calyx consisting of ten leaves.
Decidua folia, leaves that fall off in winter.
Declinatus caulis, a stalk bending toward the earth.
Decompositum folium, when a petiole once divided connects many folioles.
Decumbens, lying down,
Decurrens folium, a leaf running down, is applied to the base of a sessile leaf extending itself downward along the stem, beyond the proper termination of the leaf.
Decursive folium pinnatum, a pinnated leaf, wherein the bases of the foliole are continued along the sides of the petiolus.
Decussata folia, } leaves growing in pairs, and opposite
Decussated leaves, } to each other.
Deflexus ramus, a branch bent a little downward.
Deflorata stamina, stamina that have shed their farina.
Defoliatio, the falling of the leaves.
Deltoides folium, a leaf like the Greek Δ.
Demersa folia, leaves sunk in the water.
Dentata folia, leaves having horizontal points of the same consistence with the leaf, and standing at a little distance from each other.
Dependens folium, a leaf pointing toward the ground.
Depressum folium, a leaf pressed down, when the sides rise higher than the disk.
Dichotomi caulis, forked stalks, when the divisions come by two and two.
Dicotyledones, plants whose seeds have two cotyledons, that are the placenta of the embryo plant, and afterward the seed leaves.
Didymæ antheræ, twin antheræ, *i.e.* when they occur by two on each filament.
Didynamia, the superiority of two.
Differmia folia, leaves on the same plant of different forms.
Diffusi caules, the branches of a stalk spread different ways.
Digitatum folium, a fingered leaf, *i.e.* when the apex of a petiole connects many folioles.
Dimidiatum, halved.
Dipetalous, consisting of two petals.
Diphyllous, consisting of two leaves.
Discus, a disk, the middle part of a radiate compound flower.
Dispermous plants, plants producing their seeds by two.
Dissecta folia, leaves cut into divisions.
Dissepimentum, a partition of the fruit, which divides the pericarpium into cells.
Dissiliens siliqua, a pod that bursts with elasticity.
Distans verticullus, a species of inflorescence, wherein the whorls of verticillate flowers stand at a great distance from one another.
Disticha folia, leaves in two rows, on two sides of the branches only.
Divaricati rami, branches standing wide from each other in different directions.
Divergentes rami, branches widening gradually.
Dodrans, the 7th degree in the Linnæan scale for measuring the parts of plants, or nine Parisian inches.
Dodrantalis, nine inches long.
Dolabriforme folium, a leaf resembling an ax.
Dorsalis arista, an awn fixed to the back of the gluma.
Drupa, a pulpy pericarpium.
Duplica radix, a double root; a species of bulbous root, consisting of two solid bulbs.
Duplicato serratum folium, a leaf sawed double, with lesser teeth within the greater.

E.

Ebracteatus, without a bractea.
Ecaudata corolla, a corolla without a tail or spur.
Echinatum pericarpium, a pod beset with prickles, like a hedgehog.
Efflorescentiæ tempus, the time of efflorescence, when a plant shows its first flowers.
Elliptical, resembling an oval.
Emarginated, terminated by a notch.
Enervia folia, leaves having no apparent nerves.
Enneapetala corolla, a flower consisting of nine petals.
Enodis, having no knots or joints.
Ensatæ, plants having sword shaped leaves.
Ensiformia folia, leaves shaped like a two edged sword, tapering toward the point.
Epiphyllospermous, bearing the fruit on the back of the leaf.
Equitantia folia, leaves riding, *i.e.* when their sides approach so, that the outer embrace the inner.
Erectus, upright, perpendicular.
Erosum folium, a gnawed leaf, *i.e.* when the margin appears as if it were gnawed or bitten.
Exserta stamina, stamina standing forth, when they appear above the corolla.
Exstipulatus, without stipulæ.
Exsuccum folium, a leaf whose substance is dry.

Extrafoliaceæ stipulæ, stipulæ growing on the outside of the leaves.

F.

Farctum folium, a stuffed leaf.
Fasciata planta, a plant with many stalks grown together, like a bundle.
Fascicular, consisting of fleshy parts connected to the base without the intervention of threads.
Fascicularis radix, a bundled root, *i.e.* tuberous roots growing in bundles.
Fasciculata folia, bundled leaves; growing in bunches.
Fastigiati pedunculi, peduncles pointed at the apex.
Fauces, } the jaws or opening between the segments of
Faux, } the corolla, where the tube terminates.
Fibrosa radix, a fibrous root.
Filamentum, from filum, a thread, the part that supports the antheræ.
Filiform, thread shaped.
Fimbricata petala, fringed petals.
Fissum folium, a leaf split half way down.
Fistulosus caulis, a hollow stem.
Flabellatum folium, a fan shaped leaf.
Flaccidus pedunculus, the footstalk of a slender flower.
Flagellum, a twig or shoot like a whip.
Fleshy, filled with a firm pulp.
Flexosus caulis, a stalk having many turnings or bendings, taking a different direction at every joint.
Floralia folia, floral leaves, that immediately attend the flower.
Floralis gemma, a flower bud.
Flos, a flower.
Flosculus, a little flower.
Foliaceæ glandulæ, glands growing on the leaves.
Foliaris cirrhus, a tendril growing from a leaf.
Foliaris gemmatio, a leaf bud.
Foliatio plantæ, the complication of the leaves whilst folded within the bud.
Foliatus caulis, a leafy stalk.
Folifera gemma, a bud producing leaves.
Foliolum, a little leaf, one of the single leaves, several of which united constitute a compound leaf.
Foliosum capitulum, a leafy head, *i.e.* covered with leaves amongst the flowers or tops of the plant.
Folium, a leaf.
Folliculus, a little bag.
Fornicatum petalum, a vaulted or arched petal.
Frequens planta, a common plant, growing every where.
Frondescentiæ tempus, the season when the leaves of plants are unfolded.
Frondosus cordex, a species of trunk composed of a branch and a leaf blended together.
Fructescentiæ tempus, the time when a plant scatters its ripe seeds.
Fructificatio, the temporary part of a vegetable appropriated to generation, terminating the old plant and beginning the new.
Frustranea, to no purpose.
Frutex, a shrub.
Fruticosus caulis, a shrubby stalk.
Fugacissima petala, petals of short duration.
Fulcratus caulis, a branch having a prop.
Fulcrum, a prop or support.
Furcata, forked.
Fusiform, spindle shaped.

G.

Galea, a helmet applied to the corolla of the class gynandria.
Galeatum labium, the lip of a flower, shaped like a helmet.
Geminæ stipulæ, stipulæ growing in pairs.
Geminatus pedunculus, a double footstalk growing from one point.
Gemmiparous, bearing buds.
Geniculatus, jointed.
Geniculæ, little joints.
Germen, a sprout or bud.
Gibbum folium, a leaf bunching out.
Glaber, smooth, having an even surface.
Glabrous, of a slippery nature.
Gladiata siliqua, a sword shaped pod.
Glandulæ, glands, or secretory vessels.
Glandulifera scabrities, a kind of bristly roughness on the surface of some plants, on which there are minute glands at the extremity of each bristle.
Glareosi loci, gravelly places.
Glaucophyllus, an azure coloured leaf.
Globosa radix, a round root.
Globularis scabrities, a species of glandular roughness, scarce visible to the naked eye, the small grains of which are exactly globular.
Glochoides, the small points of the pubes of plants. Linnæus applies this term only to the hami triglochoides, with three hooked points.
Glomeratæ spicæ, flowers crowded together in a globular form.
Gluma, a husk or chaff.
Glutinocity, a slippery juice like glue or paste.
Gramina, grasses.
Granulatæ radices, } consisting of many little knobs, like
Granulated roots, } seeds or grain, attached to one another by small strings.
Gymnospermous, naked seeded.
Gynandria, male and female parts united.

H.

Hamosæ setæ, hooked bristles.
Hamus, a hook; an accuminated crooked point.
Hastata folia, leaves resembling the head of a spear.
Hemisphericus calyx, a half round flower cup.
Herba, an herb; the part of the vegetable arising from the root, terminated by the fructification, and comprehending the stem, leaf, props, and hybernacula.
Herbaceæ plantæ, perennial plants, which annually perish down to the root.
Herbacei caules, stalks that die annually.
Hexagonus caulis, a stalk with six angles.
Hexapetalæ corollæ, flowers consisting of six petals.
Hexaphyllus calyx, a flower cup consisting of six leaves.
Hians corolla, a gaping flower.
Hirsutus, rough, hairy.
Hispidus caulis, a stalk covered with strong fragile bristles.
Holeraceæ, pot herbs.
Horizontalis flos, a horizontal flower, growing with its disk parallel to the horizon.
Hybridæ plantæ, mule plants.
Hypocrateriformis corolla, a monopetalous flower, shaped like a cup or salver.

I. J.

Imberbis corolla, a flower without a beard.
Imbricatus, tiled, *i.e.* when the scales of a stalk, or flower cup, lie over one another like tiles upon a house.
Immutatæ, unaltered.
Impar, odd, applied to a pinnated leaf terminating in an odd lobe.
Inane, filled with spongy matter.
Inanis caulis, a hollow or empty stalk.
Incana folia, leaves covered with whitish down.
Incisa folia, leaves cut into irregular segments.
Incompletus flos, an imperfect flower without petals.
Incrassati pedunculi, footstalks that increase in thickness as they approach the flowers.
Incumbens anthera, an anthera affixed to the filament sideways.
Incurvatus caulis, a stalk bowed toward the earth.
Indivisum folium, an undivided leaf.
Inerme folium, a leaf unarmed, *i.e.* without prickles.
Inferus flos, a flower whose receptacle is situated below the germen.
Inflated, puffed out like a bladder.
Inflexa folia, leaves bending inward to the stem.
Infundibuliform, shaped like a funnel.
Insertus petiolus, a footstalk inserted into the stem.
Integrum folium, an undivided leaf.
Integerrimum folium, an entire leaf, whose margin is destitute of incisions.
Interfoliaceus pedunculus, a flower stalk arising from between opposite leaves.
Interrupta spica, a spike of flowers, interrupted by small clusters of flowers between the larger ones.
Interruptum folium pinnatum, the large folioles of a winged leaf, interrupted alternately by pairs of smaller ones.
Intorsion, twisting to one side.
Intrafoliaceæ stipulæ, stipulæ growing on the inside of the leaves of a plant.
Inundata loca, is applied by Linnæus to places that are overflowed only in winter.
Involucellum, a partial involucrum.
Involucrum, a cover.
Involuta folia, leaves rolled in, *i.e.* when their lateral margins are rolled spirally inward on both sides.
Irregularis flos, an irregular flower.
Juba, a crest of feathers.
Iulus, a catkin.

K.

Kernel, a seed covered with a shell.
Kidney shaped, having a notch cut out of the base, without posterior angles.

L.

Labiatus flos, a lipped flower.
Lacera folia, leaves whose margin is cut into segments, as if rent or torn.
Laciniæ, segments or divisions.
Laciniatum folium, a leaf cut into irregular segments.
Lactescentia, milkiness.
Lacunosa folia, leaves deeply furrowed by the veins being sunk below the surface.
Lacustres plantæ, plants which grow in lakes.
Lævis, smooth, having an even surface.
Lamina, a thin plate, the upper expanded part of a polypetalous flower.
Lana, wool, a species of pubescence which covers the surface of plants.
Lanatum folium, a woolly or downy leaf.
Lanceolatum folium, a lance shaped leaf.
Lappet, the superior spreading part of a monopetalous corolla.
Laterales flores, flowers coming from the sides.
Laxus caulis, a loose or slender stalk.
Leguminous plants, plants whose seeds are enclosed in pods.
Lenticularis scabrities, a species of glandular scabrities, in the form of lentils.
Leprosus, spotted like a leopard.
Liber, the inner rind of a plant.
Lignosus caulis, a woody stem.
Lignum, wood.
Ligulated, } a flower whose petals are tubulated at the
Ligulatus flos, } base, plain on the outside, linear toward the middle, and widest at the extremity, in form of a bandage.
Liliaceous, like a lily.
Limbus, a border, the upper expanded part of a monopetalous flower.
Linea, a line, the second degree in the Linnæan scale for measuring plants; the 12th part of an inch.
Lineare folium, a narrow leaf, whose opposite margins are almost parallel.
Lineata folia, leaves whose superficies are marked with parallel lines, running lengthwise.
Lingulatum folium, a leaf shaped like a tongue.
Lobata folia, } leaves divided to the middle into parts
Lobed leaves, } that stand wide from each other, and have their margins convex.
Loculamentum, a cell, a division of a capsula.
Locus foliorum, the particular part of a plant to which the leaf is affixed.
Lomentaceous, like bean meal.
Longiusculus, somewhat long.
Longum perianthium, a long perianthium, *i.e.* when the tube of the calyx is equal in length to that of the corolla.
Lucidum folium, a clear shining leaf.
Lunata folia, moon shaped leaves, round and hollowed at the base like a half moon.
Lunulated, shaped like a crescent.
Luridus, pale, wan, or dismal.
Lyratum folium, a leaf shaped like a lyre.

M.

Marcescens corolla, a flower withering on the plant.
Margo folii, the margin of the leaf.
Masculus flos, a male flower containing antheræ, but no stigma.
Masked flower, a flower gaping, but shut close between the lips.
Mas planta, a male plant.
Matrix, a seed vessel.
Medulla, marrow, the pith of a plant.
Membranacea folia, leaves which have no distinguishable pulp between their surfaces.
Membranatus caulis, a stalk covered with thick membranes.
Miliaria scabrities, a species of glandular roughness on some plants, like grains of millet.

Milky plants, plants whose juices are white, red, or yellow.
Monocotyledones, plants whose seeds have a single cotyledon.
Monoecia, one house.
Monopetalous, having but one petal.
Monophyllous, consisting of one leaf.
Monospermous, having one seed.
Mucronatum folium, a leaf terminating in a sharp point.
Multifidum folium, a leaf divided into many linear segments.
Multiflorous, bearing many flowers.
Multipartitum folium, a leaf divided into many parts.
Multisiliquæ, plants with many pods.
Muricatus caulis, a stalk whose surface is covered with sharp points, like the murex.
Muticous, without a beard or prickle.

N.

Naked, without bristles or hairs.
Natans folium, a leaf which swims on the surface of water.
Navicularis valvula, the valve of a seed vessel resembling a ship.
Nervosum folium, a leaf whose surface is full of nerves or strings.
Nervous, having unconnected small vessels, like nerves, running from the base to the top.
Nidulantia semina, seeds in the pulp of a berry.
Nitidum folium, a bright glossy leaf.
Nucleus, a kernel.
Nudus, naked.
Nutans caulis, a nodding stalk.

O.

Obcordatum petalum, a heart shaped petal, with its apex downward.
Obliquum folium, a leaf whose apex points obliquely toward the horizon.
Oblongum folium, an oblong leaf.
Obsoleta lobata folia, leaves having lobes scarcely discernible.
Obtusa folia, leaves rounded at the apex.
Obvoluta folia, leaves rolled against each other, when their respective margins alternately embrace the straight margin of the opposite leaf.
Officinales, plants used in medicine, and kept in the apothecaries' shops.
Operculum, a cover.
Oppositifolious, } branches and leaves that grow by
Oppositi rami folia, } pairs opposite each other.
Orbiculatum folium, a round leaf.
Orgya, a fathom, or six Parisian feet.
Ovale folium, an oval leaf.
Ovarium, the germen.
Ovatum folium, an egg shaped leaf.

P.

Pagina folii, the surface of a leaf.
Palea, chaff, a thin membrane rising from a common receptacle, which separates the flosculi.
Paleaceus pappus, chaffy down.
Palmata radix, a handed root.
Palmatum folium, a leaf shaped like an open hand.
Palustris, marshy or fenny.
Panduriform, shaped like a guitar.
Papilionaceous, butterfly shaped.
Papillosum folium, a leaf covered with dots or points like nipples.
Pappus, down.
Papulosum folium, a leaf whose surface is covered with pimples.
Parabolical, in form of a parabola.
Parallelum dissepimentum, the dissepiment parallel to the sides of the pericarpium.
Parasiticæ plantæ, plants that grow only out of other plants.
Partialis umbella, a partial umbel.
Partiale involucrum, a cover at the base of the partial umbel.
Partitum folium, a divided leaf.
Parvum perianthium, a little flower cup.
Patens, spreading.
Patulus calyx, a spreading cup.
Pauciflorous, having few flowers.
Pedalis caulis, a stalk a foot in height.
Pedatum folium, a species of compound leaf, whose divisions resemble the toes of the foot.
Pedicellus, a little footstalk.
Peduncularis cirrhus, a tendril proceeding from the footstalk of a flower.
Pedunculati flores, flowers growing on footstalks.
Pedunculus, the footstalk of a flower.
Peltatum folium, a leaf in which the footstalk is inserted into its disk instead of its base.
Penicilliforme stigma, a stigma in the form of a painter's pencil.
Pentagonus caulis, a five angled stalk.
Pentapetalous, consisting of five petals.
Pentaphyllous, consisting of five leaves.
Perennial, continuing for many years.
Perfecti flores, flowers having petals; the perfect flowers of Ray, Tournefort, and other botanists.
Perfoliatum folium, a leaf whose base entirely surrounds the stem, or through whose centre the stalk grows.
Perforati cotyledones, perforated cotyledons.
Perianthium, *i.e.* surrounding the flower, a species of calyx.
Pericarpium, *i.e.* round the fruit, a pod.
Perichætium, a circular tuft of fine hairlike leaves, surrounding the bases of the filaments in the musci and algæ.
Petaliforme stigma, a stigma resembling the shape of a petal.
Petaloides flos, a flower having petals.
Petiolaris cirrhus, a tendril proceeding from the footstalk of a leaf.
Petiolatum folium, a leaf growing on a footstalk.
Petiolus, a little footstalk.
Pileus, a hat or bonnet, the orbicular expansion of a mushroom, which covers the fructification.
Pilosum folium, a leaf whose surface is covered with long distinct hairs.
Pinnatifidum folium, a winged leaf; applied to simple leaves whose laciniæ are transverse to the rachiæ.
Pinnatum folium, a winged leaf.
Pixidatum folium, a kind of foliage where one leaf is let into another by a joint.
Planipetalous, with plain flat petals.
Planum folium, a plain flat leaf.

Plicatum folium, a plaited leaf.
Plumata seta, a feathered bristle.
Plumosus pappus, a kind of soft down.
Pollex, a thumb, the length of the first joint of the thumb, or a Parisian inch.
Polycotyledones, many cotyledons.
Polygamia, many marriages.
Polygynia, many females.
Polypetalous, consisting of many petals.
Polyphillous, consisting of many leaves.
Polyspermous, containing many seeds.
Polystachius culmus, a stalk of grass having many spikes.
Præmorsa radix, a bitten root, ending abruptly.
Prismaticus calyx, a triangular flower cup.
Procumbent, lying on the ground.
Prominulous, jetting out beyond the valves.
Pronum discum folii, a leaf with its face downward.
Proprium involucrum, an involucrum at the base of an umbellated flower.
Pulposum folium, a pulpy leaf.
Pulveratum folium, a leaf powdered with a kind of dust like meal.
Punctatum folium, a leaf sprinkled with hollow dots or points.
Putamineous, like a shell.

Q.

Quadrangulare folium, a leaf with 4 prominent angles in the edge of its disk.
Quadrifidum folium, a leaf divided into 4 parts.
Quadrijugum folium, a leaf having 4 pair of folioles.
Quadrilobum folium, a leaf consisting of 4 lobes.
Quadripartitum folium, a leaf consisting of 4 divisions down to the base.
Quaterna folia, verticillate leaves, having four in each whorl.
Quina folia, verticillate leaves by fives.
Quinatum folium, a digitate leaf with 5 folioles.
Quinquangulare folium, a leaf with 5 prominent angles in the edge of its disk.
Quinquefidum folium, a leaf consisting of 5 divisions, with linear sinuses, and straight margins.
Quinquejugum folium, a pinnated leaf with 5 pair of folioles.
Quinquelobum folium, a leaf with 5 lobes.
Quinquepartitum folium, a leaf consisting of 5 divisions down to the base.

R.

Rachis folii pinnati, the middle rib of a winged leaf, to which the folioles are affixed.
Radiatus flos, a species of compound flowers, in which the florets of the disk are tubular, and those of the radius ligulate.
Radicalia folia, leaves proceeding immediately from the root.
Radicans caulis, a stalk bending to the ground, and taking root where it touches the earth.
Radicata folia, leaves shooting out roots.
Radius, a ray, the ligulate margin of the disk of a compound flower.
Ramea folia, leaves that grow only on the branches, and not on the trunk.
Ramosissimi caules, stalks abounding with branches irregularly disposed.
Ramosus caulis, a stalk having many branches.
Ramus, a branch of a tree.
Reclinatum folium, a leaf bending downward.
Recurvatum folium, a leaf bent backward.
Reflexus ramus, a branch bent back toward the trunk.
Remotus verticillus, a species of inflorescence, wherein the whorls of flowers and leaves stand at a distance from one another.
Reniforme folium, a kidney shaped leaf.
Repandum folium, a leaf having a bending or waved margin without any angles.
Repens caulis, a creeping stalk, either running along the ground, or on trees or rocks, and striking roots at certain distances.
Repens radix, a creeping root extending horizontally.
Reptans flagellum, a twig creeping along the ground.
Restantes pedunculi, footstalks remaining after the fructification has fallen off.
Resupinatio florum, the upper lip of a flower facing the ground, and the lower lip turned upward.
Resupinatum folium, a leaf, the lower disk of which looks upward.
Retroflexus ramus, a branch bent in different directions.
Retrofractus pedunculus, a footstalk bent back toward its insertion, as if it were broken.
Retusum folium, a leaf with its apex blunt.
Revolutum folium, a leaf rolled back.
Rhombeum folium, a leaf whose shape nearly resembles a rhombus.
Rhomboideum folium, a leaf of a geometrical figure, whose sides and angles are unequal.
Rigidus caulis, a stiff or rigid stem.
Rimosus caulis, a stalk abounding with clefts and chinks.
Ringens, grinning or gaping.
Rosaceus flos, a flower whose petals are placed in a circle like those of a rose.
Rostellum, a little beak.
Rotaceous, like a wheel.
Rotatus limbus corollæ, a wheel shaped flower, expanded horizontally, having a tubular basis.
Rotundatum folium, a roundish leaf.
Rubra lactescentia, red milkiness.
Ruderata loca, rubbishy places.
Rugosum folium, a rough or wrinkled leaf.

S.

Sagittatum, arrow shaped.
Sarmentosus caulis, the shoot of a vine, naked between each joint, and producing leaves at the joints.
Scaber caulis, a scabby and rough stalk, having tubercles.
Scabrities, a species of pubescence, composed of particles scarcely visible, on the surface of plants.
Scandens caulis, a climbing stalk.
Scariosa folia, leaves dry on the margin, that sound when touched.
Scorpioides flos, a flower resembling the tail of a scorpion.
Scutellum, a species of fructification which is orbicular, concave, and elevated in the margin.
Scyphifer, cup bearing.
Secretoria scabrities, a species of glandular roughness on the surface of some plants.
Securiformis pubescentia, a species of pubescence on some plants, the bristles resembling an ax.
Seminalia folia, seed leaves.

Semiteres caulis, a half round stalk, flat on one side.
Sempervirens folium, an evergreen leaf.
Sena folia, leaves growing in sixes.
Sericeum folium, a leaf whose surface is of a soft silky texture.
Serratum folium, a sawed leaf.
Sessile folium, a leaf growing immediately to the stem, without any footstalk.
Setæ, bristles.
Setacea folia, leaves shaped like bristles.
Simplex caulis, a single stem.
Sinuatum folium, a leaf whose sides are scalloped.
Solidus caulis, a solid stalk.
Solitarius pedunculus, a solitary flower stalk, *i.e.* when only one proceeds from the same part.
Solutæ stipulæ, loose straw.
Sparsus, scattered without order.
Spathaceous, like a sheath.
Spatulatum folium, a leaf in the form of a spatula.
Spica, a spike; a species of inflorescence in grasses, resembling an ear of corn.
Spicula, a little spike.
Spinæ, thorns, or rigid prickles.
Spinescent, hard and prickling.
Spinosus caulis, a stalk with strong prickles, whose roots proceed from the wood of the stem, and from the surface of the bark.
Spirales cotyledones, seminal leaves twisted spirally.
Spithama, a span, or seven Parisian inches.
Splendentia folia, shining leaves.
Squamosa radix, a scaly root.
Squarrosum, rough, scaly, or scurfy.
Staminens flos, flowers having stamina, but no corolla.
Staturninatæ, an order of plants in the former Fragmenta Methodi Naturalis of Linnæus.
Stellata folia, leaves surrounding a stem like the rays of a star.
Stellatæ setæ, bristles arising from a centre in form of a star.
Sterilis flos, a barren flower; masculus of Linnæus.
Stigma, a mark, the apex of the pistillum.
Stimuli, stings.
Stipitatus pappus, a kind of trunk that elevates the down and connects it with the seed.
Stipulares glandulæ, glands produced from stipulæ.
Stolo, a shoot which, running on the surface of the ground, strikes root at every joint.
Striati caules, culmi, &c. channelled streaks running lengthwise in parallel lines.
Strictus caulis, a straight stiff shoot.
Strigæ, ridges or rows.
Stylus, the style, from stylus a pillar.
Submersum folium, the leaf of an aquatic plant, sunk under the surface of the water.
Subramosus caulis, a stalk having few branches.
Subrotundum folium, a leaf almost round.
Subulatum folium, an awl shaped leaf.
Suffrutex, an under shrub.
Sulcatus caulis, or culmus, a stalk deeply furrowed lengthwise.
Superus flos, a flower whose receptacle stands above the germen.
Supra axillaris pedunculus, the footstalk of a flower whose insertion is above the angle formed by the branch.
Supra decomposita folia, composite leaves which have little leaves growing on a subdivided footstalk.
Supra foliaceus pedunculus, the footstalk of a flower inserted into the stem immediately above the leaf.
Surculus, a twig, the stalk of a moss.
Swob, a legumen or pod.
Syngenesia, generating together.

T.

Tegumentum, a cover.
Teres caulis, a cylindrical stalk.
Tergeminum folium, a leaf three times double, when a dichotomus petiolus is subdivided, having two foliola on the extremity of each division.
Ternata folia, leaves in whorls by threes.
Tessalatum folium, a checkered leaf, whose squares are of different colours.
Tetradynamia, the superiority of four.
Tetragonus caulis, a square stalk.
Tetrapetalous, consisting of four petals.
Tetraphyllous, consisting of four leaves.
Tetraspermous, producing four seeds.
Thalamus, a bed, the receptacle.
Theca, a sheath.
Tomentosus, covered with a whitish down like wool.
Tomentum, a species of woolly or downy pubescence, covering the surface of some plants.
Torosum pericarpium, a brawny protuberance, like the swelling of the veins, when a pericarpium is bunched out by the enclosed seeds.
Torta corolla, a flower with the petals twisted.
Tortillis arista, a twisted awn.
Transversum dissepimentum, the dissepiment at right angles with the sides of the pericarpium.
Trapeziforme folium, a leaf having four prominent angles, whose sides are neither equal nor opposite.
Triangulare folium, a triangular leaf.
Tricocca capsula, with three cells, and a single seed in each.
Tricuspidated, three pointed.
Trifidum folium, a leaf divided into three linear segments, having straight margins.
Triflorus, bearing three flowers.
Trigonus caulis, a three sided stalk.
Trihilatum semen, a seed having three eyes.
Trijugum folium, a winged leaf with three pairs of foliola.
Trilobum folium, a leaf with three lobes.
Trilocular folium, a leaf having the pericarpium divided into three loculaments.
Trinervum folium, a leaf having three strong nerves running from the base to the apex.
Trioecia, three houses.
Tripartitum folium, a leaf divided into three parts down to the base.
Tripetalous, consisting of three petals.
Tripetaloideæ, three petalled.
Triphyllous, consisting of three leaves.
Tripinnatum folium compositum, a leaf having a triple series of pinnæ, or wings.
Triplinerve folium, a leaf having three nerves running from the base to the apex.
Triquetrum folium, or triquetra caulis, a leaf, or stalk, having three plain sides.
Trispermous, three seeded.

Triternatum folium compositum, a compound leaf when the divisions of a triple petiolus are subdivided into threes.
Trivalve pericarpium, a pod consisting of three valves.
Truncatum folium, a leaf having its apex as it were cut off.
Truncus, the body or stem of a tree.
Tuberculatus, having pimples or tubercles.
Tuberculum, a little pimple.
Tuberosa radix, a knobbed root.
Tubulatum perianthium, a tubular flower.
Tubulosi flosculi, tubular florets nearly equal.
Tubus, a tube.
Tunicatus radix, a species of bulbous root, having coats lying one over another from the centre to the surface; as in the onion, &c.
Turbinatum pericarpium, a kind of pod shaped like a top, narrow at the base, and broad at the apex.
Turgidum legumen, a swollen pod.
Turiones, the young buds of pines.

V. U.

Viginalis, sheathed.
Vaginans folium, a leaf like a sheath.
Valvula, a valve.
Venosum folium, a leaf whose whole surface is run over by veins.
Ventricosa spica, a spike narrowing at each extremity, and bellying out in the middle.
Ventriculosus calyx, a flower cup bellying out in the middle, but not in so great a degree as ventricosus.
Verrucosa capsula, a capsule having little knobs or warts on its surface.
Versatilis anthera, an anthera fixed by the middle on the point of the filament, and so poised as to turn like the needle of a compass.
Verticalia folia, leaves so situated that their base is perpendicular above the apex.
Verticillated branches, flowers, or leaves; such as surround the stem, like the rays of a wheel.
Vesicula, a little bladder.
Vesicularis scabrities, a kind of glandular roughness, resembling vesicules.
Vexillum, a standard, the upright petal of a papilionaceous flower.
Villosus, covered with soft hairs.
Virgatus caulis, a stalk shooting out.
Viscidum folium, a clammy leaf.
Viscositus, clamminess.
Uliginosa loca, boggy places.
Umbella, an umbel or umbrella.
Umbellatus flos, an umbellated flower.
Umbellula, a little umbel.
Umbilicatum folium, a leaf shaped like a navel.
Uncinatum stigma, a hooked stigma.
Undatum folium, a waved leaf, whose surface rises and falls in waves toward the margin.
Undulata corolla, a flower whose petals are waved.
Unguis, a nail or claw; that part of a petal that is joined to the receptacle.
Unicus flos, a single flower.
Unicus radix, a single root.
Uniflorus pedunculus, a footstalk with one flower.
Unitelateralis, growing on one side.
Universalis umbella, an universal umbel.
Volubilis caulis, a twining stalk.
Urecolata corolla, a pitcher shaped flower.
Urens caulis, or folium, a stalk or leaf burning, or stinging, as nettles.
Utricula, a species of glandular secretory vessels, on the surface of various plants.

W.

Waved, having the disk alternately bending up and down in obtuse plaits.
Wedge shaped, growing narrower toward the base.
Whirl, or Whorl, { leaves, flowers, &c. surrounding a stalk or trunk at the joints in great numbers.

BOTE, *bota*, in our old law books, signifies recompense or amends: thus man bote, is a compensation for a man slain. There are likewise house bote and plough bote, privileges to tenants, of cutting wood for making ploughs, repairing tenements, and likewise for fuel.

BOTRYCHIUM, in botany, a genus of the class cryptogamia, order of filices. There are four species, natives of America. 1. B. virginicum, 2. B. fumarioides, 3. B. obliquum, 4. B. dissectum. (*a*)

BOTTOM, in navigation, is used to denote as well the channel of rivers and harbours, as the body or hull of a ship: thus, in the former sense, we say a gravelly bottom, clayey bottom, sandy bottom, &c. and in the latter sense, a British bottom, a Dutch bottom, &c. By statute, certain commodities imported in foreign bottoms, pay a duty called petty customs, over and above what they are liable to if imported in British bottoms.

BOTTOMRY, in commerce, a marine contract for the borrowing of money upon the keel or bottom of a ship; that is, when the master of a ship binds the ship itself, that if the money be not paid by the time appointed, the creditor shall have the ship.

Bottomry is also where a person lends money to a merchant, who wants it in traffic, and the lender is to be paid a greater sum at the return of the ship, standing to the hazard of the voyage; on which account, though the interest be greater than what the law commonly allows, yet it is not usury, because the money being furnished at the lender's hazard, if the ship perishes he shares in the loss.

It is enacted by 19 Geo. II. cap. xxxvii. that after August 1, 1746, every sum of money lent on bottomry, upon the ships of any subjects to or from the East Indies, shall be lent only on the ship, or the merchandises laden on board her, and so expressed in the condition of the bond; and the benefit of salvage shall be granted to the lender, his agents, &c. who only shall have a right to make assurance on the money lent; and no borrower of money on bottomry shall recover more on any assurance than the value of his interest on the ship or effects, exclusive of the money borrowed. And if the value of his interest does not amount to the money borrowed, he shall be responsible to the lender for the surplus, with lawful interest for the same, together with the assurance, and all charges whatsoever, &c. notwithstanding the ship and merchandise shall be totally lost.

BOTTONY. A cross bottony, in heraldry, terminates at each end in three buds, knots, or buttons, resembling, in some measure, the trefoil; on which account Segoing, in his Tresor Héraldique, terms it croix trefflée. It is the badge of the order of St. Maurice.

BOTTS. See Oestris.

BOUGIE, in surgery, originally a wax taper, but the term is now generally applied to several instruments which are used by surgeons in diseases of the urinary passage. See Surgery.

BOULTINE, a term which workmen use for a moulding, the convexity of which is just one fourth of a circle; being the member next below the plinth in the Tuscan and Doric capitals.

BOUNTY, in commerce, a premium paid by the government to the exporters of certain British commodities, on their taking oath, or, in some cases, giving bond, not to reland the same in England.

Bounties, as they respect the fisheries, are either perpetual or temporary. The former are payable on the export of pilchards, cod fish, ling whether wet or dried, salmon, white herrings, red herrings, and dried red sprats, being of British fishery and curing. The latter are payable on the tonnage of ships carrying on the British and Greenland fisheries, on the quantity of fish taken in the British and Newfoundland fisheries, on the quantities of oil, blubber, and whale fins, taken in the southern whale fishery. The bounty on cordage manufactured in Great Britain, is 2*s*. 4$\frac{3}{4}$*d*. per cwt. Bounties have been granted by several statutes on the exportation of corn, when it does not exceed stipulated prices at the port of exportation. Those trades only require bounties, in which the merchant is obliged to sell his goods for less than they cost him; and the bounty is given to compensate this loss, and to encourage him to continue, or perhaps to commence, a trade that may be important to the interests of the country.

Bounty, queen Anne's, for augmenting poor livings under 50*l*. per annum, consists of the produce of the first fruits and tenths, after the charges and pensions payable out of the same are defrayed. To remedy the inconveniences that result from an absurd statute enforcing the residence of the clergy, by stat. 44 Geo. III. c. 2. the sum of 8000*l*. was granted out of the consolidated fund to the governors of queen Anne's bounty, for the relief of curates deprived of their cures on account of the residence of incumbents.

BOURIGNONISTS, the name of a sect among the Low country protestants, being such as follow the doctrine of Antoinette Bourignon, a native of Lisle, and apostate from the Roman catholic religion. The principles of this sect bear a very near resemblance to those of the quietists and quakers.

BOUTANT, or Arch boutant, in architecture, a flat arch or part of an arch abutting against the reins of a vault, to prevent its giving way. A pillar boutant is a large chain or pile of stone, made to support a wall, terrace, or vault.

BOW, *arcus*, a weapon of offence made of steel, wood, horn, or other elastic matter. The use of the bow is, without all doubt, of the earliest antiquity. It has likewise been the most universal of all weapons, having obtained amongst the most barbarous and remote people, who had the least communication with the rest of mankind. The figure of the bow is pretty much the same in all countries where it has been used; for it has generally two inflections or bendings, between which, in the place where the arrow is drawn, is a right line. The Grecian bow was in the shape of an Σ, of which form we meet with many, and generally adorned with gold or silver. The Scythian bow was distinguished from the bows of Greece and other nations by its incurvation, which was so great as to form a half moon or semicircle. The Persians had very great bows made of reeds, probably the bamboo; and the Indians had also, not only arrows, but bows made of the reeds or canes of that country; the Lycian bows were made of the cornel tree; and those of the Ethiopians, which surpassed all others in magnitude, were made of the palm tree.

Though it does not appear that the Romans made use of bows in the infancy of their republic, yet they afterward admitted them as hostile weapons, and employed auxiliary archers in all their wars.

In drawing the bow, the primitive Grecians did not pull back their hand toward the right ear, according to the fashion of modern ages, and of the ancient Persians, but placing their bow directly before them, returned their hand upon the right breast. This was also the custom of the Amazons.

The bow is a weapon of offence amongst the inhabitants of Asia, Africa, and America, at this day; and in Europe, before the invention of fire arms, a part of the infantry were armed with bows. Lewis XI. first abolished the use of them in France, introducing in their place the halberd, pike, and broad sword. The long bow was formerly in great use in England, and many laws were made to encourage it. The parliament under Henry VII. complained of the disuse of long bows, heretofore the safeguard and defence of this kingdom, and the dread and terror of its enemies.

Bow, among builders, a beam of wood or brass, with three long screws that direct a lath of wood or steel to any arch; chiefly used in drawing draughts of ships and projections of the sphere; or wherever it is requisite to draw large arches.

Bow *of a ship*, that part which begins at the loof, and compassing the ends of the stem, finishes at the sternmost part of the forecastle.

That part upon the right hand side of the stem, to a person on deck and looking forward, is called the starboard bow, and on the left hand side is called the larboard bow.

Bow, *weather*, is that part of the bow toward the wind when a ship is close hauled; and the other part is called the lee bow.

Bow, *on the*, an expression to denote the position of any object, as a ship, the land, &c. appearing in the direction of some particular part of the bow. If a ship is sailing directly toward the object, it is said to be right ahead; if not, the object is said to be on the starboard or larboard, or on the weather or lee bow.

BOWER, in the sea language, the name of an anchor carried at the bow of a ship. There are generally two bowers, called first and second, great and little, or best and small bower.

BOWLINE, in sea language, a rope fastened near the middle of the leech, or perpendicular edge of the principal square sails, by three or four subordinate parts called bridles, and leading forward toward the bow, whence it derives its name. It is always used when the wind is so unfavourable, that the sails must be all braced sideways, or close hauled to the wind: in this situation, the bowlines are employed to keep the weather or windward

edges of the principal sails right forward and steady, without which they would be perpetually shivering, and rendered incapable of service. The bowline is fastened by two, three, or four ropes, like a crow's foot, to as many parts of the sail; only the mizen bowline is fastened to the lower end of the yard. This rope belongs to all sails, except the spritsail and sprit-topsail. The use of the bowline is to make the sails stand sharp, or close, or by a wind.

Sharp the bowline, is hale it tawt, or pull it hard. *Hale up the bowline*, that is, pull it harder forward on. *Check* or *ease*, or *run up* the bowline, that is, let it be more slack.

BOWSE, in the sea language, signifies as much as to hale or pull. Thus bowsing upon a tack, is haling upon a tack. Bowse away, that is, pull away all together.

BOWSPRIT, or *boltsprit*, a kind of mast, resting slopewise on the head of the main stem, and having its lower end fastened to the partners of the foremost, and further supported by the fore stay. It carries the spritsail, sprit-topsail, and jack staff; and its length is usually the same with that of the foremast.

BOWYERS, artificers whose employment or occupation it is to make bows. There is a company of bowyers in the city of London, first incorporated in 1623.

BOX, or *box tree*. See Buxus.

BOYAU, in fortification, a ditch covered with a parapet, which serves as a communication between two trenches. It runs parallel to the works of the body of the place, and serves as a line of contravallation, not only to hinder the sallies of the besieged, but also to secure the miners. But when it is a particular cut that runs from the trenches to cover some spot of ground, it is drawn so as not to be enfiladed, or scoured by the shot from the town.

BOYES, idolatrous priests among the savages of Florida.

BRABEJUM, the *African almond*, a genus of the monoecia order, and polygamia class of plants. In the male the corolla is four or five parted; there are four stamina inserted in the throat; the style is bifid and abortive; the hermaphrodite has a four parted corolla, revolute upward, with four stamina, one pistil with two stigmas; the fruit is a roundish drupa with a globular seed. Of this genus there is but one species, *viz.*

Brabejum stellatifolium, the star leafed African almond, a native of the Cape of Good Hope. In Europe it seldom grows above eight or nine feet high, but in its native soil is a tree of middling growth. It rises with an upright stem, which is soft, and full of pitch within, and covered with brown bark. The leaves come out all round the branches at each joint: they are indented at their edges, standing on very short footstalks. The flowers are produced toward the end of their shoots, of a pale colour inclining to white. They may be propagated, though with difficulty, by layers made in April. In winter they should have a good greenhouse; but in summer they should be placed abroad in a sheltered situation.

BRACE, in architecture, a piece of timber framed in with bevil joints, the use of which is to keep the building from swerving either way. When the brace is framed into the kinglesses, or principal rafters, it is by some called a strut.

Braces, in the sea language, are ropes belonging to all the yards of a ship, except the mizen, two to each yard, reeved through blocks that are fastened to penants, seized to the yard arms. Their use is either to square or transverse the yards.

Brace, in writing, a term used to signify a crooked line, as } , made at the end of two or more articles in an account, the amount of which is usually placed in the centre of the brace. It is used also in printing to enclose an entire passage, as a triplet in poetry.

BRACED, in heraldry, a term for the intermingling three cheoronels.

BRACHIÆUS. See Anatomy.

BRACHIALIS. See Anatomy.

BRACHIUM, *arm*. See Anatomy.

BRACHMANS, or *bramins*, a sect of Indian philosophers, known to the ancient Greeks by the name of gymnosophists. The ancient Brachmans lived upon herbs and pulse, and abstained from every thing that had life in it. They lived in solitude, without matrimony, and without property. The modern Brachmans constitute one of the casts or tribes of the Banians. They are the priests of that people, and perform their office of praying and reading the law, with several mimic gestures, and a kind of quavering voice. They believe in rewards and punishments after this life; and have so great a veneration for cows, that they look on themselves as blessed if they can but die with the tail of one of them in their hand. They have preserved some noble fragments of the knowledge of the ancient Brachmans. They are skilful arithmeticians, and calculate, with great exactness, eclipses of the sun and moon. They are remarkable for their religious austerities. One of them has been known to make a vow to wear about his neck a heavy collar of iron for a considerable time; another to chain himself by the foot to a tree, with a firm resolution to die in that place; and another to walk in wooden shoes stuck full of nails on the inside. Their divine worship consists chiefly of processions, made in honour of their deities. They have a college at Banara, a city seated on the river Ganges.

BRACHYGRAPHY, the art of short hand writing. See Tachygraphy.

BRACHYSTEMON, in botany, a genus of the class didynamia, order gymnospermia. The essential character is, cal. 5 toothed, cor. gaping, white; 4 seeded, oblong. There are 4 species. 1. B. verticillatus, a native of Pennsylvania. 2. B. muticus, a native of Carolina. 3. B. virginicus, a native of Penns. 4. B. lanceolatus, a native of Penns. They flower in August.

BRACKETS, in a ship, the small knees, serving to support the galleries, and commonly carved. Also, the timbers that support the gratings in the head are called brackets.

Brackets, in gunnery, are the cheeks of the carriage of a mortar: they are made of strong planks of wood, of almost a semicircular figure, and bound round with thick iron plates; they are fixed to the beds by four bolts, which are called bed bolts; they rise upon each side of the mortar, and serve to keep her at any elevation, by means of some strong iron bolts, called bracket bolts, which go through these cheeks or brackets.

BRACTEARIA, in natural history, a genus of tales, composed of small plates in form of spangles, each plate being either very thin, or fissile into very thin ones. See MINERALOGY.

BRADS, among artificers, a kind of nails used in building, which have no spreading heads, as other nails have. They are distinguished, by ironmongers, by six names; as joiner's brads, flooring brads, batten brads, bill brads, or quarter heads, &c. Joiner's brads are for hard wainscot; batten brads, for soft wainscot; bill brads are used when a floor is laid in haste, or for shallow joists subject to warp. See NAIL.

BRADYPUS, or *sloth*, a genus of animals of the order of bruta. The generic character is: 1st, Bradypus tridactylus, or three toed sloth. The general appearance of the sloth is extremely uncouth; the body is of a thick shape; the fore legs short, the hinder ones far longer; the feet on all the legs are very small, but are armed each with three most excessively strong and large claws, of a slightly curved form, and sharp pointed. The head is small; the face short, with a rounded or blunt snout, which is naked, and of a blackish colour; the eyes are small, black, and round; the ears rather small, flat, rounded, lying close to the head, and not unlike those of monkies. The hair on the top of the head is so disposed as to project somewhat over the forehead and sides of the face, giving a very peculiar and grotesque physiognomy to the animal. The general colour of the hair on all parts is a grayish brown; and the hair is extremely coarse, moderately long, and very thickly covers the body, more especially about the back and thighs. A remarkable character as to colour in this species, is a wide patch or space on the upper part of the back, of a bright ferruginous or rather pale orange colour, spotted on each side with black, and marked down the middle with a very conspicuous black stripe; wide at its origin, and gradually tapering to its extremity: it reaches more than half way down the back, and terminates in a sort of trifid mark. The tail is nearly imperceptible, being so extremely short as to be concealed from view by the fur.

The count de Buffon is not willing to allow this creature any share in contributing to the general beauty in the scale of animated nature, but considers it as an ill constructed mass of deformity, created only for misery.

Notwithstanding this appearance of wretchedness and deformity, the sloth is, perhaps, as well fashioned for its proper modes and habits of life, and feels as much happiness in its solitary and obscure retreats, as the rest of the animal world of greater locomotive powers and superior external elegance.

The sloth feeds entirely on vegetables, and particularly on leaves and fruit. Its voice is said to be so inconceivably singular, and of such a mournful melancholy, attended, at the same time, with such a peculiarity of aspect, as at once to excite a mixture of pity, and disgust: and it is added, that the animal makes use of this natural yell as its best mode of defence; since other creatures are frightened away by the uncommon sound. This, however, is far from being its only refuge; for so great is the degree of muscular strength which it possesses, that it is capable of seizing a dog with its claws, and holding it, in spite of all its efforts to escape, till it perishes with hunger; the sloth itself being so well calculated for supporting abstinence, that the celebrated Kircher assures us of its power in this respect having been exemplified by the very singular experiment of suffering one, which had fastened itself to a pole, to remain in that situation, without any sustenance, upward of forty days. This extraordinary animal is an inhabitant of the hotter parts of South America. It is nearly as large as a middle sized dog. See Plate XXXIII. Nat. Hist. fig. 62.

2d. Bradypus didactylus, or two toed sloth, is also a native of South America; and it is asserted, on good authority, that it is likewise found in some parts of India, as well as in the island of Ceylon. In its general appearance, as well as in size, it bears a considerable resemblance to the former species: it is, however, somewhat more slender in its shape, covered with smoother or less coarse and harsh hair, and is of a more uniform or less varied tinge, and, in particular, is strikingly distinguished, as a species, by having only two claws on the fore feet; it is also a much more active animal, and, even when imported into Europe, has been known, according to the testimony of the count de Buffon, to ascend and descend from a tall tree several times in a day; whereas the three toed sloth with difficulty performs that operation in a whole day, and can scarcely crawl a few hundred yards in the space of many hours.

3d. Bradypus ursinus, or ursine sloth, is by far the largest species: it is a native of India, and has been but lately introduced to the knowledge of European naturalists. It was brought from the neighbourhood of Patna in Bengal. This animal has, at first sight, so much of the general aspect of a bear, that it has actually been considered as such by some observers: but it is no otherwise related to the bear than by its size and habit, or mere exterior outline.

It is about the size of a bear, and is covered all over, except on the face, or rather the snout, which is bare and whitish, with long, shaggy, black hair; which on the neck and back is much longer than elsewhere. On the fore part of the body the hair points forward; on the hinder part backward. The eyes are very small: the ears rather small, and partly hid in the long hair of the head. It is totally destitute of incisores or front teeth: in each jaw there are two canine teeth of a moderate size. The nose or snout is of a somewhat elongated form; it also appears as if furnished with a sort of transverse joint, or internal cartilage, which admits of a peculiar kind of motion in this part.

It is a gentle and good natured animal; it feeds chiefly on vegetables and milk, is fond of apples, and does not willingly eat animal food, except of a very tender nature, as marrow, which it readily sucked from a bone presented to it. Its motions are not, as in the two former species, slow and languid, but moderately lively; and it appears to have a habit of turning itself round and round every now and then, as if for amusement, in the manner of a dog when lying down to sleep. It is said to have a propensity to burrowing under the ground.

BRAG, a game at cards, wherein as many may partake as the cards will supply; the eldest hand dealing three to each person at one time, and turning up the last card all round. This done, each gamester puts down three stakes, one for each card. The first stake is won by the best card turned up in the dealing round, beginning from the

ace, king, queen, knave, and so downward. When cards of the same value are turned up to two or more of the gamesters, the eldest hand gains; but it is to be observed that the ace of diamonds wins, to whatever hand it is turned up.

The second stake is won by what is called the brag, which consists in one of the gamesters challenging the rest to produce cards equal to his: now it is to be observed, that a pair of aces is the best brag, a pair of kings the next, and so on; and a pair of any sort wins the stake from the most valuable single card. In this part consists the great diversion of the game; for, by the artful management of the looks, gestures, and voice, it frequently happens that a pair of fives, treys, or even duces, out brags or induces the holder to throw up a higher pair, and even some pairs royal, to the no small merriment of the company. The knave of clubs is here a principal favourite, making a pair with any other card in hand, and with any other two cards a pair royal.

The third stake is won by the person who first makes up the cards in his hand one and thirty; each dignified card going for ten, and drawing from the pack, as usual in this game.

BRAGANTIA racemosa, in botany, a plant of the class gynandria, order hexandria, cal. none, cor. 1 petaled, tubo globose, furrowed lengthwise, 4 celled, 4 valved. (*b*)

BRAIL, or Brails, in a ship, are small ropes made use of to furl the sails across: they belong only to the two courses and the mizen sail.

BRAIN. See Anatomy.

BRAN, the skins or husks of corn, especially wheat ground, separated from the corn by a sieve or boulter. It is of wheat bran that starch makers make their starch. The dyers reckon bran among the not colouring drugs, and use it for making what they call the sour waters, with which they prepare their dyes.

BRANCHIÆ, *gills*, in the anatomy of fishes, the parts corresponding to the lungs of land animals, by which fishes take in and throw out again a certain quantity of water impregnated with air. All fishes, except the cetaceous ones and the lamprey, are furnished with these organs of respiration, which are always eight in number, four on each side the throat. That next the heart is always the least, the rest increasing in order as they stand near the head of the fish.

Each of these gills is composed of a bony lamina, in form of a semicirele, for the most part; and on its convex side stand the leaves or lamellæ, like so many sickles. The whole convex part of the lamellæ is beset with hairs, which are longest near the base, and decrease gradually as they approach toward the point. There are also hairs on the concave side of the lamellæ, but shorter than the others, and continued only to its middle. The convex side of one lamina is fitted into the concave side of the next superior one; and all of them are connected together by means of a membrane, which reaches from their base half way their height, where it grows thicker, and in some measure resembles a rope. The rest of the lamina is free, and terminates in a very fine and flexible point. The use of these gills seems to be to receive the blood protruded from the heart into the aorta, and convey it into the extremities of the lamellæ; whence being returned by veins, it is distributed over the body of the fish.

BRANCHIARUM *foramina*, apertures of the gills. In most fishes there is only one aperture; in the cartilaginous ones, these apertures are ten in number, five on each side; and in the lamprey there are no less than fourteen of these apertures, seven on each side.

Cetaceous fishes have no aperture of this kind; and the reason seems to be because they are furnished with lungs.

BRANCHIDÆ, in Grecian antiquity, priests of the temple of Apollo, which was at Didymus in Ionia.

BRANCHIOSTEGI, in ichthyology, one of the five general orders of fishes into which they were formerly divided: the rays of the fins are bony: they have no bones or ossiculæ in the branchiæ or gills.

BRANDY, a spirituous and inflammable liquor, extracted from wine and other liquors by distillation.

Brandy is prepared in many of the wine countries of Europe, and with peculiar excellence in Languedoe, in Anjou, and other parts of the south of France, whence is the Coniac brandy. In distilling brandy, the strong heavy wines are preferred. It is expected that all wines used for this purpose should yield at least one sixth of their quantity of spirit. The apparatus is composed of three parts: the alembie, or boiler, the capital fitted on the top of the boiler to receive the spirituous vapour, and a worm immersed in cold water, in which the vapour is condensed, and flows out in the form of distilled spirit. In general, the slower the process, and the smaller the stream of spirit from the worm pipe, the finer and better is the brandy. That part of the spirit which comes over first has the strongest, richest, and highest flavour. See Aleohol.

Brandy is naturally clear and colourless as water. The different shades of colour which it has in commerce arise partly from the casks in which it is kept, but chiefly from the addition of burnt sugar, saunders wood, and other colouring matters that are intentionally added by the manufaeturer, and which are neither of advantage nor disadvantage to the quality of the spirit.

Besides the brandy made of wine, there is some also made of beer, cider, syrups, sugar, molasses, fruit, grain, &c. however, these are not properly called brandy, but go under the general denomination of spirits.

BRASIL wood, or Brazil wood, an Amerieau wood of a red colour, and very heavy. It is denominated variously, according to the places whence it is brought: thus we have brazil from Fernambuco, Japan, Lamon, &c. See Cæsalpina.

This wood must be chosen in thiek pieces, close, sound, without any bark on it, and such as, upon splitting, of pale becomes reddish, and, when chewed, has a saecharine taste. It is much used in turning work, and takes a good polish; but its chief use is in dyeing.

When the sulphuric aeid is added slowly to a fresh watery deeoction of Brazil wood, a small quantity of red preeipitate falls down, and the liquor becomes yellow. Nitric aeid produees a similar change; but the liquor is orange. Most of the other aeids produce red precipitates. The alkalies restore in part the colour of the liquor. The action of the solutions of tin and of alum is the most important. Alum gives a fine red precipitate in great abundanee; and in this manner a fine crimson lake and carmine are sometimes prepared, which consist of alumina, united

with the natural colour of the wood. Nitromuriat of tin, added to the decoction, separates the whole of the colouring matter, which falls down in great abundance, united with the oxide of tin, and the liquor remains colourless. The solutions of iron blacken Brazil wood, manifesting the presence of gallic acid.

The colour of Brazil wood, though very beautiful, is fugitive, and is readily darkened and rendered purple by alkalies, or by soap that contains an alkali. When it is used by dyers, they employ acids and tin to fix the colour.

BRASS is a factitious metal made of copper and zinc, in proper proportions. It is of a beautiful yellow colour, more fusible than copper, and not so apt to tarnish. It is malleable, and so ductile that it may be drawn out into wire. Its density is greater than the mean density of the two metals. By calculation it ought to be 7.63 nearly, whereas it is actually 8.39; so that its density is increased by about 1-10th. The ancients do not seem to have known accurately the difference between copper, brass, and bronze. They considered brass as only a more valuable kind of copper, and therefore used the word *æs* to denote either. They called copper *æs cyprium*, afterward, *cyprium;* and this in process of time was converted into *cuprum*.

The method of preparing brass is as follows: The zinc having been calcined and ground fine as flour, is mixed with fine charcoal, and incorporated, by means of water, into a mass: this being done, about seven pounds of zinc is put into a melting pot that will contain about a gallon, and over that about five pounds of copper; this pot is let down into a wind furnace, where it remains for eleven hours, in which time it is converted into brass. The metal then is cast, either into plates or lumps; forty-five pounds of crude zinc will produce thirty pounds when calcined or burnt. Sometimes brass shruff is used instead of copper; but that is not always to be procured in quantities sufficient, it being no other than a collection of old brass.

Pure brass is not malleable, unless when it is hot; for when it is cold it will break; and after it has been melted twice, it will be no longer in a condition to bear the hammer at all: but in order to render it capable of being wrought, they put seven pounds of lead to an hundred weight of brass, which renders it more soft and pliable.

The most important properties of brass are that its colour is much brighter and nearer approaching to gold than copper. It is also more fusible, and less subject to rust, and to be acted upon by a vast variety of substances which corrode copper: it is also more capable of extension, and peculiarly adapted for wire. Mr. Smeaton found that 12 inches in length of cast brass at 32°, expanded by 180° of heat, $\frac{225}{10000}$ parts: brass wire, under the same circumstances, expanded $\frac{232}{10000}$. The expansion of hammered copper is only $\frac{204}{10000}$, but that of zinc is $\frac{313}{10000}$; so that brass holds a middle place in this respect between its two component metals.

There is a vast variety in the proportions of the different species of brass used in commerce; nor is it easy to determine whether the perfection of this alloy depends on any certain proportion of the two metals. In general the extremes of the highest and lowest proportions of zinc are from 12 to 25 parts in the 100. The ductility of brass is not injured with the highest proportion. This metal is much used in the escapement wheels, and other nicer parts of watch making; and bars of brass very carefully made will fetch for this work almost any price.

The use of brass is of very considerable antiquity. Most of the ancient genuine relics are composed of various mixtures of brass with tin and other metals, and are rather to be denominated bronzes.

The best proportion for brass guns is said to be 1000 pounds of copper, 900 pounds of tin, and 600 pounds of brass, in 11 or 12 hundred weight of metal.

The best brass guns are made of malleable metal, not of pure copper and zinc alone; but worse metals are used to make it run closer and sounder, as lead and pot metal. See CANNON.

BRASS, *Corinthian*, has been famous in antiquity, and is a mixture of gold, silver, and copper.

BRASS *colour*, one prepared by the braziers and colourmen to imitate brass. There are two sorts of it, the red brass or bronze, and the yellow or gilt brass: the latter is made only of copper filings, the smallest and brightest that can be found; with the former they mix some red ochre, finely pulverized: they are both used with varnish.

BRASSICA, the cabbage, a genus of the class and order tetradynamia siliquosa. The essential character is: calyx erect, converging; seeds globular; a gland between the shorter stamens and the pistil, and between the longer and the calyx.

There are sixteen species, *viz.*

1. Brassica orientalis; perfoliate cabbage. 2. Brassica austriaca; Austrian cabbage. 3. Brassica campestris; yellow field cabbage. 4. Brassica arvensis; purple field cabbage. 5. Brassica alpina; Alpine cabbage. 6. Brassica napus; wild cabbage, rape, or navew. 7. Brassica rapa; turnip. 8. Brassica oleracea; common cabbage. 9. Brassica chinensis; Chinese cabbage. 10. Brassica violacea. 11. Brassica polymorpha. 12. Brassica erucastrum; wild rocket. 13. Brassica eruca; garden rocket. 14. Brassica vesicaria. 15. Brassica muralis; wall rocket. 16. Brassica Richerii.

The first has the petals white; all the leaves smooth; stem leaves ovate, blunt at the end, heart shaped at the base, smooth, glaucous, perfectly entire; petals white with a tinge of straw colour; siliques slender, pointing upward, and approaching the stem; root fusiform. Mr. Hudson affirms, that this is very nearly allied to the campestris; and Dr. Stokes thinks it probable that the plant of hort. ups. supposed to be the B. orientalis of Tournefort and our European species, are distinct. There is certainly great confusion in the three first species of brassica; and in a genus so subject to vary, perhaps mere local differences may have been exalted into species.

It is a native of corn fields and cliffs, in the Levant, about Montpellier; in Germany, Switzerland, Austria, Carniola, Piedmont, &c. In England, near Harwich; Bardsey near Orford, Suffolk; Godstone and Maresfield, Sussex: annual, flowering in June.

The second is a native of Austria, a biennial: root white, rather woody, sometimes branched, about half a foot long, very thin, with an acrid smell: stem in the wild plant commonly single, in the cultivated or garden ones generally more, about two feet high; leaves entire, rounded at the ends, thick, glaucous, embracing the stalk, very smooth. The flowers are yellow, and open in small num-

bers at once. The siliques are about three inches long, smooth, sharp, and parallel, or nearly so, with the stalk, standing in an upright manner. It is a plant which naturally grows in rough uncultivated places, and in fields.

3. Root annual; root leaves lyrate, slightly hispid; stem leaves smooth and even; corolla yellow, never white. It grows among summer corn, in the north of Europe; and in some parts of Sweden it is a common weed.

4. Stem a foot high, smooth and even, flexuose, branched, perennial at bottom; leaves smooth, quite blunt, rather fleshy; calyx closed, smooth, with a double protuberance at the base. Native of the south of Europe, in moist fields.

5. This differs from the foregoing sort in having a narrower stem; the leaves more tender and longer; those next the ground on long petioles: but it differs principally in having almost upright, white petals, and the small flower of a Turritis. Native of Germany and Sweden.

6. Root biennial; stem somewhat branched, cylindrical, smooth, from a foot to two feet in height; root leaves lyrate; stem leaves smooth, glaucous, sessile, stem clasping, of an oblong heart shaped figure, very slightly toothed on the edges; calyx yellowish green, spreading as in Sinapis. The silique has frequently three or four warty excrescences. The roots, when cultivated, may be eaten, but have a stronger taste than the turnip. Under the title of rape or coleseed, it is much cultivated in the isle of Fly, and some parts of England, for its seed, from which the rape oil is drawn; and for feeding cattle. What remains after the oil is expressed, is called oil cake or rape cake. It is very efficacious manure, and is sold from four to six pounds a ton. It is not this but the lint cake, or residuum of flaxseed, used in making linseed oil, that is used in fatting beasts.

Linnæus says that the navew grows wild on the sandy shores of Gotland, Holland, and England. With us it is found among corn, and on ditch banks.

7. The turnip, now so common in cultivation, is sufficiently known by its round fleshy roots. These, however, vary exceedingly in their form, size, and colour, in a cultivated state, in which only we are apt to view them.

The variations of turnip are chiefly in the root, and arise from the different soils, situations, and modes of cultivation. The varieties enumerated by Mr. Miller are, 1. the round, red, or purple topped; 2. the green topped; 3. the yellow; 4. the black rooted; 5. the early Dutch. He allows that these may be varieties accidentally obtained from seeds, although he has sown them several years, and has always found them to retain their differences. The yellow turnip seems most unlikely to have been an accidental variety, because the roots are yellow within, whereas the others have white flesh, notwithstanding they are of different colours on the outside. He thinks that the long rooted turnip is a distinct species; the form of the root, and its manner of growth, being totally different from those before enumerated. The roots are sometimes as long as those of the parsnep, and nearly of the same shape.

The general use of this root for the table and feeding of cattle is well known: and it has been a considerable improvement of light lands, particularly in the county of Norfolk, whence other counties have derived the culture. The red rooted turnip was formerly more cultivated in England than at present; but since the large green topped turnip has been introduced, all skilful farmers prefer it to the others, because the roots grow to a large size, and continue much longer good. It also grows above ground more than any of the others, which renders it preferable for feeding cattle; and being the softest and sweetest, even when very large, it is most esteemed for the table. In very severe winters, however, this is in greater danger of suffering by frost than those whose roots lie deeper, especially if the ground is not covered with snow; for when the roots are alternately frozen and thawed, they rot sooner than those which are more covered, and less tender. We have known roots of this sort which were more than a foot in diameter, boiled, and were as sweet and tender as any of the smallest roots. At Stowe, in Gloucestershire, a farmer produced four turnips weighing an hundred weight; and offered to produce, from a small given space, eighty turnips which should weigh a ton.

The next in goodness to the green topped is the red or purple topped turnip, which will also grow large, and be extremely good for some time; but the roots will become stringy much sooner than the others. The long rooted, the yellow, and the black rooted turnips are now rarely cultivated, except for the sake of variety, none of them being so good for the table or for feed as the red and green topped sorts.

The early Dutch turnip is chiefly sown in the spring, to supply the table before the others can be procured; and when drawn off young, this sort is tolerably good; but if the roots are left to grow large, they become stringy, rank, and unfit for use.

Turnip roots are reputed to relax the bowels, and to sweeten the blood; to be hurtful to pregnant and hysterical women, and to all who are subject to flatulencies. The juice well fermented, affords by distillation an ardent spirit. The rind is acrimonious. The tender tops boiled are frequently eaten in the spring as greens with meat.

8. The cabbage, as it is found in its wild state on the sea shores of Britain, has the stem leaves very much waved, and variously indented; the colour sea green, frequently with a mixture of purple; the lower ones somewhat ovate and sessile; the upper almost linear. The flowers are large; the leaflets of the calyx ovate, broad, and yellow; the siliques short and swelling.

Early in the spring the sea cabbage is preferable to the cultivated sorts; but when it is gathered on the coast, it must be boiled in two waters, to take away the saltness. When old it is said to occasion giddiness. The roots may also be eaten, but they are not so tender as those of the turnip and navew. All the different varieties of garden cabbage originate from this.

These varieties may, it should seem, be reduced to three general divisions: the first comprehending those which grow in the natural way, without forming the leaves or stalks into a head. This section or division, besides the sea cabbage or wild colewort, would comprehend the green colewort, the borecoles, and turnip cabbage. Secondly, those which form the leaves into a head, as the white cabbage, the red, the savoy, &c. Thirdly, those which form their stalks into a head, as the cauliflower, and the different varieties of broccoli. The first section might be subdivided into the wild, with broad leaves, and an

even stem; the turnip cabbage, with broad leaves and a protuberant stem; and the borecoles, with fine cut leaves, and an even stem. The second section contains the cabbages commonly so called: as the red; the numerous varieties of the white, such as the sugar loaf, the early, the foreign musk, the small Russia, the large sided, the flat topped, the Yorkshire, Scotch, American, &c. and those with wrinkled leaves, as the common savoy, the green savoy, &c. Of the borecoles in the first, and the broccoli in the third section, there are also variations in colour, the purple and the white.

The common colewort, or Dorsetshire kale, is now almost lost near London, where the markets are usually supplied with cabbage plants instead of them; these being more tender and delicate. The common colewort, indeed, is better able to resist the cold in severe winters; but it is not good till it has been pinched by frost; and our winters being generally temperate, cabbage plants are now constantly brought to market; which, if they are of the sugar loaf kind, are the sweetest greens from December to April yet known, the variegated kale excepted.

The curled coleworts or borecoles are more generally esteemed than the common one, being like that so hardy as never to be injured by cold, and at the same time much more tender and delicate: these, however, are always sweeter in severe winters than in mild seasons.

Of the heading cabbages, the red is chiefly cultivated for pickling; the common white, flat, long sided, and savoy, for winter use. The musk cabbage is almost lost, though for eating it is one of the best we have.

The early York and sugar loaf cabbages are generally sown for summer use, and are commonly called Michaelmas cabbages. The Russian cabbage was formerly in much greater esteem than at present, it being now only to be found in particular gentlemen's gardens, and rarely brought to market. The other heading cabbages, together with many others, for it would be endless to enumerate all the varieties which are perpetually rising into fame, and falling into oblivion, are cultivated chiefly for feeding cattle; for which they are certainly well adapted on strong lands; but they are undoubtedly a very exhausting crop.

The cauliflower was first brought to England from the island of Cyprus, where it is in great perfection at present; but it is supposed it was originally brought thither from some other country: most of the old writers mention it to have been brought from that island to the different parts of Europe. Although this plant was cultivated in a few English gardens long since, yet it was not brought to any degree of perfection till about the year 1680, at least not to be sold in the markets. Since the year 1700, the cauliflower has been so much improved in England, that such plants as before would have been greatly admired, are at present little regarded. It has indeed been much more improved in England than in any other parts of Europe. In France they rarely have cauliflowers till near Michaelmas; and Holland is generally supplied with them from England. In many parts of Germany they were not cultivated till within a few years past; and most parts of Europe are supplied with seeds from hence.

Purple and white broccoli are only varieties of the cauliflower; for although with care they may be kept distinct, yet if they were to stand near each other for seed, they would probably intermix. When, however, these are cultivated with care, they may be kept distinct. The variations are not occasioned by soil, but by the mixture of the farina of the anthers in the flowers; those persons, therefore, who are curious to preserve them distinct, never suffer the different sorts to stand near each other for seed.

9. Leaves oblong or oval, very like those of hound's tongue, blunt but smooth; stem leaves embracing, oblong, quite entire; flowers, as in the common cabbage, yellow; calyx longer than the claws of the petals, whence it gapes and is prominent between them; stamens longer; siliques a little compressed. Native of China.

10. This is an annual plant, which, if sown in April, will flower in July, and perfect the seeds in October. It never closes the leaves to form a head, but grows open and loose, more like the wild navew. This sort came from China, where it is cultivated as an esculent plant. There are two or three varieties of it, and it is as changeable as our common cabbage.

11. This species is a native of Siberia, and is an annual plant. The root is thin and fibrose. The stems numerous, growing oblique, two feet or more in length, smooth, and branching upward; the leaves are of dissimilar forms, but in general are linear, lanceolate, thick, and alternate; those on the stalk generally dentated; the denticles nearly subulate. The shoots are leafy, proceeding from the axillas of the branches, so as to cause a kind of clustering appearance; the flowers are pale yellow. It is a plant which varies extremely in the appearance of its leaves.

12. Root annual, fusiform; stems many, from a foot to eighteen inches high and more, round, smooth, sometimes having a few hairs and small red dots, bright or glaucous green; branches alternate; flowers in a long, loose, terminating raceme; peduncles alternate, round, smooth, one flowered; corollas yellow, with dark yellow and green veins; siliques spreading, obtusely quadrangular. Native of the southern countries of Europe, in sandy fields, by waysides, and on walls; flowering from June to August.

13. Root annual: stem angular, upright, branching, two feet high and more; leaves smooth, pulpy, with a leafy nerve, and three or four pair of pinnas, larger as they approach the nerve, confluent, oblong, acute, toothed; the outer largest, ovate, or rhomboidal, often semibifid and semitrifid; calyx erect, livid, with the leaflets, especially two of them, gibbous; claw of the petals erect, long; border broad, roundish, lemon colour, with black veins, sometimes white; siliques on short peduncles; seeds round on one side and flat on the other. Native of Switzerland, Austria, and Piedmont. It was formerly much cultivated in the gardens as a sallad herb, but at present is little known, having been long rejected on account of its strong ungrateful smell. It also stood in the list of medicinal plants, but is now seldom used, though it is reckoned a strong diuretic.

14. Root annual, spindle shaped; leaves lanceolate, pinnatifid toothed, smooth above; stem hairy, branching; racemes erect, terminating; corollas yellow, with darker veins; calyx cylindrical; but in the fruit it becomes inflated and permanent. It differs from the foregoing, in

having a calyx under the fruit, inflated like a bladder; leaves not lyrate but lanceolate; siliques hispid backward, not smooth; calyxes permanent till the fruit is ripe, not deciduous. Native of Spain and Aleppo.

15. Root perennial, somewhat woody, penetrating deep into walls; stem a foot and a half high, branched, round, at bottom somewhat woody and perennial; leaves pinnatifid and jagged, smooth, spreading, having a disagreeable smell; petals rather large, twice the length of the calyx, yellow; the two glands on the outside of the filaments are unusually long, externally bent in at the top; the other two shorter and roundish; silique an inch and a half long, round, marked on each side with a prominent line.

It grows on old buildings and walls in many parts of England, as Yarmouth, Chester, &c.

16. Root woody, perennial; root leaves elliptic, obtuse, obscurely sinuate, angular; petiole channelled, the length of the leaves; stem round, striated, hollow, a cubit and a half high, simple or a little branched; stem leaves few, distant, like the others, but on shorter petioles, and scarcely angular; flowers in umbels; petals ovate, yellow, scarcely emarginate; veins darker; siliques tortuose, subquadrangular, drawn to a point at both ends. The whole plant is very smooth, tender, juicy, and glaucous. Native of the south of France, and the mountains of Piedmont.

BRAULS, Indian cloths with blue and white stripes: they are otherwise called turbans, because they serve to cover those ornaments of the head, particularly on the coast of Africa.

BRAWN, the flesh of a boar soused or pickled; for which end the boar should be old; because the older he is, the more horny will the brawn be.

The method of preparing brawn is as follows: the boar being killed, it is the flitches only, without the legs, that are made brawn; the bones of which are to be taken out, and then the flesh sprinkled with salt, and laid in a tray, that the blood may be drawn off: then it is to be salted a little, and rolled up as hard as possible. The length of the collar of brawn, should be as much as one side of the boar will bear; so that when rolled up it may be nine or ten inches diameter.

The collar being thus rolled up, is to be boiled in a copper, or large kettle, till it is so tender, that you can run a straw through it: then set it by, till it is thoroughly cold, and put it into the following pickle. To every gallon of water, put a handful or two of salt, and as much wheat bran: boil them together, then drain the bran as clear as you can from the liquor: and when the liquor is quite cold, put the brawn into it.

BRAZED, in heraldry, a term serving to describe three cheverons, one clasping another.

BRAZIER, an artificer who makes kettles, pans, candlesticks, and other kitchen utensils in brass. Some of the articles manufactured by the working brazier are beaten out with the hammer, and united in their several parts by solder; others are cast, but those which are cast belong more properly to the business of the founder, excepting the polishing and finishing, which require the art of the brazier.

BRAZING, the soldering or joining two pieces of iron together by means of thin plates of brass, melted between the pieces that are to be joined. If the work is very fine, as when two leaves of a broken saw are to be brazed together, they cover it with pulverized borax, melted with water, that it may incorporate with the brass powder, which is added to it: the piece is then exposed to the fire without touching the coals, and heated till the brass is seen to run.

BREACH, in fortification, a gap made in any part of the works of a town by the cannon or mines of the beseigers, in order to make an attack upon the place. To make the attack more difficult, the beseiged sow the breach with crow feet, or stop it with chevaux-de-frize.

A practicable breach is that where the men may mount and make a lodgement, and ought to be 15 or 20 fathoms wide. The besiegers make their way to it by covering themselves with gabions, earth bags, &c.

Breach, in a legal sense, is where a person breaks through the condition of a bond or covenant, on an action upon which the breach must be assigned; and this assignment must not be general but particular, as in an action of covenant for not repairing houses, it ought to be assigned particularly what is the want of reparation; and in such certain manner that the defendant may take an issue.

BREAD, *panis*, a mass of dough, kneeded and baked in an oven. See Baking.

BREAD FRUIT. See Artocarpus.

Bread room, in a ship, that destined to hold the bread or biscuit. The boards of the bread room should be well joined and caulked, and even lined with tin plates or matts. It is also proper to warm it well with charcoal for several days before the biscuit is put into it; since nothing is more injurious to the bread than moisture.

BREAK, in the art of war, or to break ground, is to open the trenches before a place.

BREAKERS, a name given to those billows that break violently over rocks lying under the surface of the sea. They are distinguished both by their appearance and sound, as they cover that part of the sea with a perpetual foam, and produce a hoarse and terrible roaring, very different from what the waves usually have in a deeper bottom. When a ship is unhappily driven among breakers, it is hardly possible to save her; as every billow that heaves her upward serves to dash her down with additional force, when it breaks over the rocks or sands beneath it.

BREECHINGS, in the sea language, the ropes with which the great guns are lashed or fastened to the ship's side. They are thus called, because made to pass round the breech of the gun.

BREDEMEYERA floribunda, in botany, a shrub of the class diadelphia, order octandria: the calyx 3 leaved; corolla papilionaceous, vexillo 2 leaved, drupa 2 celled: flourishes in the woods of the Caraccas. (*b*)

BREEZE, a shifting wind, that blows from sea or land for some certain hours in the day or night.

The sea breeze which takes place in tropical climates, is only sensible near the coasts; it commonly rises in the morning, about nine, proceeding slowly in a fine small black curl on the water, toward the shore; it increases gradually till twelve, and dies about five. Upon its ceasing, the land breeze commences, which increases till 12 at night, and is succeeded in the morning by the sea breeze again.

In some countries, the sea breezes appear to be only the efforts of the trade wind, as at Barbadoes, and

in many places between the tropics, where the general wind, if not impeded by mountains or islands, blows fresh in the day time, but after sunset, the terrestrial exhalations being precipitated, produce a new wind, which is not only able to make head against the trade wind, but to repel it from their coasts. The sea breezes do not all come from the same point of the compass, but from different points as the land lies. Breezes are more constant in summer than in winter, and more between the tropics than in the temperate zone. Breezes differ from the trade winds, as the former occur daily, and are perceived only near the shore, whereas the latter are periodical at certain seasons, and blow at a distance from the land.

BREHONS, hereditary judges belonging to the inferior provincial kings, and also to the nobles or chieftains, among the ancient Irish, by whom justice was administered, and controversies decided.

BRENTA, a liquid measure used at Rome.

BRENTUS, a genus of coleopterous insects, having the head protracted into a very long projecting snout, beyond the middle of which the antennæ, which are moniliform, are inserted. There are several species, as the anchorago, Plate, Nat. Hist. fig. 63. barbicornis, &c.

BREST SUMMERS, in timber buildings, are pieces in the outward, into which the girders are framed: this, in the ground floor, is called a cell; and, in the garret floor, a beam.

BREST, or Breast, in architecture, a term sometimes used for the member of a column, more usually called torus.

BRETHREN, *and sisters of the free Spirit*, an appellation assumed by a new sect which sprung up in the thirteenth century, and gained many adherents in Italy, France, and Germany. They derived their name from the words of St. Paul, Rom. viii. verse 1—14. They maintained that all things flowed by emanation from God; and that by the power of contemplation, they were united to the Deity, and thereby acquired a glorious and sublime liberty, both from the lusts and the instincts of nature; hence they inferred that the person who was thus absorbed in the Deity, became a part of the Godhead, and was the son of God in the same sense that Christ was. They treated with contempt all Christian ordinances, and all external acts of religion, as unsuitable to the state of perfection at which they had arrived.

BREVE, in law, is any writ directed to the chancellor, judges, sheriffs, or other officers, whereby a person is summoned, or attached, to answer in the king's courts, &c.

Breve perquirere, the purchasing of a writ or license for trial in the king's courts: whence comes the present usage of paying 6s. 8d. fine to the king in suit, for money due on bond, where the debt is 40l. and of 10s. where it is 100l. &c.

Breve, in music, a note or character of time in the form of a diamond, or square, without any tail, and equivalent to two measures, or minims.

BREVET, in the French customs, denotes the grant of some favour or donation from the king, in which sense it partly answers to our warrant, and partly to letters patent.

BREVIARY, a daily office, or book of divine service, in the Romish church. It is composed of matins, lauds, first, third, sixth, and ninth vespers, and the compline, or post communio.

The institution of the breviary is not very ancient: there have been inserted in it the lives of the saints, full of ridiculous and ill attested stories, which gave occasion to various reformations of it, by several councils, particularly those of Trent and Cologn; by several popes, particularly Pius V. Clement VIII. and Urban VIII. also by several cardinals and bishops, each lopping off some extravagances, and bringing it nearer to the simplicity of the primitive offices.

Originally every person was obliged to recite the breviary every day; but by degrees the obligation was reduced to the clergy only, who are enjoined under penalty of mortal sin and ecclesiastical censures, to recite it at home, when they cannot attend in public. In the fourteenth century there was a particular reserve granted in favour of bishops, who were allowed, on extraordinary occasions, to pass three days without rehearsing the breviary.

This office was originally called cursus, and afterward the breviarum; which latter name imports, that the old office was abridged, or rather that this collection is a kind of abridgment of all the prayers.

BREVIATOR, an officer under the eastern empire, whose business it was to write and translate briefs. At Rome those are still called breviators, or abbreviators, who dictate and draw up the pope's briefs.

BREVIBUS a rotulis liberandis, a writ or command to a sheriff, to deliver to his successor, the county, with the appurtenances, and the rolls, writs, and other things to his office belonging.

BREVIER, among printers, a small kind of type, or letter, between nonpareil and burgeois.

BREWING, the art of making beer or ale. The art of brewing is undoubtedly a part of chymistry, and depends on fixed and invariable principles. These principles have never yet been thoroughly investigated, and on that account a just and certain theory has not been obtained. We shall, however, give the best rules, as far as practical observation and experience have hitherto gone, for the information of those who have not had the opportunity of attending to the subject.

Malt liquor is essentially composed of water, the soluble parts of malt and hops, and of yeast. There are several kinds of malt, which are distinguished by their colour, and the colour depends upon the mode of malting and drying. Whether the pale or the brown malt is used, it must be coarsely ground, or bruised between rollers, which is rather to be preferred.

The next consideration in brewing is the quality of the water to be employed; and here soft water is universally allowed to be preferable to hard, both for the purposes of mashing and fermentation. Transparency is however more easily obtained by the use of hard than soft water. But it is not well adapted to the brewing of porter, or such beers as require a fulness of palate, as in the London brewery, and some country situations. The purity of water is determined by its lightness; and in this respect, distilled water only can claim any material degree of perfection. Rain water is the purest of all naturally produced; but having once descended to the surface of the earth, it is li-

able to a variety of intermixtures unfavourable to the purposes of brewing. With regard to others, though a matter of considerable importance, no precise rule can be laid down. Where there is liberty of choice, a preference should doubtless be given to that water, which from natural purity is equally free from saline substances and vegetable putrefaction, has a soft fulness upon the palate, is totally flavourless, inodorous, and colourless; whence it is the better prepared for the reception and retention of such qualities as brewing is to communicate.

The first step in the process of brewing is mashing, which is performed in a large circular wooden vessel, shallow in proportion to its extent, and furnished with a false bottom, pierced with small holes, and moveable or fixed a few inches above the real bottom. There are two side openings in the interval between the real and false bottom; to one is fixed a pipe for the purpose of conveying water into the tun, and the other for drawing the liquor out of it. The malt is to be strewed evenly over the false bottom of the same tun, and then by means of the side pipe, a proper quantity of hot water is introduced from the upper copper. The water rises up through the malt, or as it is called, the grist, and when the whole quantity is introduced, the mashing begins, the object of which is to effect a perfect mixture of the malt with the water, so that the soluble parts may be extracted by it: for this purpose, the grist is incorporated with the water by means of iron rakes, and then the mass is beaten and agitated by long flat wooden poles resembling oars, which are either worked by the hand or by machinery connected with the steam engine or some other moving power. When the mashing is completed, the tun is covered in to prevent the escape of the heat, and the whole is suffered to remain still, in order that the insoluble parts may separate from the liquor: the side hole is then opened, and the clear wort allowed to run off, slowly at first, but more rapidly as it becomes fine, into the lower or boiling copper.

The chief thing in mashing is the temperature of the mash, which depends on the heat of water, and on the state of the malt. If the water was let in upon the grist, boiling hot, the starch which it contains would be dissolved and converted into a gelatinous substance, in which all the other parts of the malt, and most of the water, would be entangled, beyond the possibility of recovery by any after process. The most eligible temperature appears to be from 185° to 190° of Fahrenheit: for the first mashing the heat of the water must be somewhat below this temperature, and lower in proportion to the dark colour of the malt made use of; for pale malt, the water may be 180°, but for brown, it ought not to be more than 170°. The wort of the first mashing is always by much the richest in saccharine matter; but to exhaust the malt, a second and a third mashing is required, in which the water may be safely raised to 190° or upward. The proportion of wort to be obtained from each bushel of malt, depends entirely on the proposed strength of the liquor. It is said that 25 or 30 gallons of good table beer may be taken from each bushel of malt. For ale and porter of the superior kinds, only the produce of the first mashing, or six or eight gallons is to be employed. Brewers make use of an instrument called a saccharometer, to ascertain the strength and goodness of the wort. This instrument is a kind of hydrometer, and shows the specific gravity of the wort, rather than the exact quantity of saccharine matter which it contains.

We now come to the boiling and hopping; and if only one kind of liquor is made, the produce of the three mashings is to be mixed together; but if both ale and table beer are required, the wort of the first, or of the first and second mashings is appropriated to the ale, and the remainder is set aside for the beer. All the wort destined for the same liquor, after it has run from the tun, is transferred to the large lower copper, and mixed with a certain proportion of hops. The better the wort, the more hops are required. In private families, a pound of hops is generally used to every bushel of malt: but in public breweries, a much smaller proportion is deemed sufficient. When both ale and table beer are brewed from the same malt, the usual practice is to put the whole quantity of hops in the ale wort, which having been boiled some time, are to be transferred to the beer wort, and with it to be again boiled.

When the hops are mixed with the wort in the copper, the liquor is made to boil, and the best practice is to keep it boiling as fast as possible, till upon taking a little of the liquor out, it is found to be full of small flakes like those of curdled soap. The boiling copper is in common breweries uncovered: but in many on a very large scale, it is fitted with a steam tight cover, from the centre of which passes a pipe, that terminates by several branches in the upper or mashing copper: the steam, therefore, produced by the boiling, instead of being wasted, is let into the cold water, and thus raises it very nearly to the temperature required for mashing, besides impregnating it very sensibly with the essential oil of the hops, in which the flavour resides.

When the liquor is boiled, it is discharged into a number of coolers, or shallow tubs, in which it remains until it becomes sufficiently cool to be submitted to fermentation. It is necessary that the process of cooling should be carried on as expeditiously as possible, particularly in hot weather; and for this reason, the coolers in the great brewhouses are very shallow. Liquor made from pale malt, and which is intended for immediate drinking, need not be cooled lower than 75 or 80 degrees; of course this kind of beer may be brewed in almost the hottest weather; but beer brewed from brown malt, and intended to be kept, must be cooled to 65 or 70 degrees, before it is put into a state of fermentation. Hence the spring and autumn have ever been deemed the most favourable for the manufacture of the best malt liquor.

We now come to the tunning and barrelling: from the coolers the liquor is to be transferred into the working tun, and with it is to be mixed a gallon of yeast to four barrels of beer. In four or five hours the fermentation begins, and it requires from 18 or 20 hours to 48, before the wort is fit to be put into barrels. In the barrels the fermentation again goes on, and during a few days, a copious discharge of yeast takes place from the bung hole; care must be taken that the barrels are carefully filled up every day with fresh liquor: this discharge gradually becomes less, and in about a week it ceases; at which time the bung hole is closed, and the liquor is fit for use after it has stood a certain time according to its strength, and the temperature at which it has been fermented.

Brewing, among distillers, denotes the method of extracting the more soluble parts of vegetables with hot water, and thus procuring a solution or decoction fitted for vinous fermentation. In this sense brewing is a necessary step toward distillation. A fermentable solution, fit for yielding a spirit, is obtainable from any vegetable, under proper management. Thus sugar, treacle, and other inspissated vegetable juices, which totally unite with water, are better adapted to fermentation, than roots, fruits, or herbs, in substance, the grains, or even the malt itself; all which dissolve, but very imperfectly, in hot water. Malt is, however, generally used in England, and brewed for this purpose: the worst malt will serve for distillation; and the infusion or wort without the addition of hops, and the trouble of boiling, is here directly cooled and fermented. See Distilling.

BREYNIA, in botany, a genus of the polyandria dioecia class and order of plants. The essential character is, male calyx one leaved, five parted; corolla none; nect. five glands; filaments five, very short; anthers roundish. Female calyx and corolla as in the male; pist. germ globose; style none; stigmas five; per. caps. five celled; seeds solitary. There is one species, a native of New Caledonia.

BRIBERY, the receiving, or offering, any undue reward, by or to any person whatsoever, whose ordinary profession or business relates to the administration of public justice, in order to incline him to do a thing against the known rules of honesty and integrity: it also signifies the taking or giving a reward for offices of a public nature.

As to the punishment of bribery, by the common law, bribery in a judge, was looked upon as an offence of so heinous a nature, that it was sometimes punished as high treason. 3 Inst. 148. And all other kinds of bribery are punishable by fine and imprisonment; which may also be inflicted on those who offer a bribe though not taken. Blacks. 143. 2 Inst. 147.

BRICIANI, a military order, instituted by St. Bridget, queen of Sweden.

BRICK, a reddish earth, of the aluminous or argillaceous kind, formed into long squares, by means of a wooden mould, and then baked or burnt. In the East they baked their bricks in the sun; the Romans used them unburnt, only leaving them to dry for four or five years in the air.

Bricks, among us, are various, according to their various forms, dimensions, uses, method of making, &c. the principal of which are, compass bricks, of a circular form, used in steyning of walls: concave, or hollow bricks, on one side flat like a common brick, on the other hollowed, and used for conveyance of water; feather edged bricks, which are like common statute bricks, only thinner on one edge than the other, and used for penning up the brick pannels in timber buildings; cogging bricks are used for making the indented works under the coping of walls built with great bricks: coping bricks, formed on purpose for coping of walls: Dutch or Flemish bricks, used to pave yards, or stables, and for soap boilers' vaults, and cisterns: clinkers, such bricks as are glazed by the heat of the fire in making: sandal or samel bricks, are such as lie outmost in a kiln or clamp, and consequently are soft and useless, as not being thoroughly burnt: great bricks are those twelve inches long, six broad, and three thick, used to build fence walls: plaster or buttress bricks, have a notch at one end, half the breadth of the brick; their use is to bind the work which is built of great bricks; statute bricks, or small common bricks, ought, when burnt, to be nine inches long, four broad, and two and a half thick.

The art of brickmaking is, in almost all its branches, regulated by different acts of parliament. Bricks may be made of pure clay, or of clay mixed with sand or ashes, or with both. The clay is first moistened and tempered with water, to render it fit for moulding into bricks. Then several persons are usually employed in making a single brick: these are called a gang, and they consist of one or two men, a woman, and two children, to each of which is assigned a different department in the occupation. A gang in full work will make many thousand bricks in the course of a week. When the bricks are made and sufficiently dried, they are burnt in a kiln. The great art in this part of the process, is required in piling the bricks, so that the fire may circulate through every course, and in all directions. Bricks when finished are of different colours, according to the clay of which they are made; the most beautiful are the white bricks manufactured at Woolpit in Suffolk.

BRICKLAYER, one who lays bricks in the building of edifices of any kind. Tilers and bricklayers were incorporated 10 Eliz. under the name of master and wardens of the society of freemen of the mystery and art of tilers and bricklayers.

BRIDEWELL, in Bridge street, Blackfriars, is a foundation of a singular nature, partaking partly of the hospital, the prison, and the workhouse. It was founded by Edward VI. who presented the place, which had formerly been the palace of king John, to the city of London, with 700 marks of land, bedding and other furniture. Several youths are sent to this hospital as apprentices to manufacturers who reside there, and when they have faithfully served their time of seven years, they are presented with their freedom, and ten pounds each for carrying on their respective trades.

BRIDGE, a work of masonry or timber, consisting of one or more arches, built over a river, canal, or piece of water, for the convenience of crossing the same.

Bridges are a sort of edifices very difficult to execute, on account of the inconvenience of laying foundations and walling under water. The parts of a bridge are the piers, the arches, the pavement, or way over for cattle and carriages, the footway on each side, for foot passengers, the rail or parapet, which encloses the whole, and the butments or ends of the bridge on the bank.

The conditions required in a bridge are, that it shall be well designed, and suitably decorated. The piers of stone bridges should be equal in number, that there may be one arch in the middle, where commonly the current is strongest; their thickness is not to be less than a sixth part of the span of the arch, nor more than a fourth; they are commonly guarded in the front with angular starlings, to break the force of the current. As the piers of bridges always diminish the bed of a river in case of inundations, the bed must be sunk or hollowed in proportion to the space taken up by the piers, (as the waters gain in depth what they lose in breadth,) which otherwise conduce to wash away the foundation and endanger the piers; to prevent this, they sometimes diminish the current, either

by lengthening its course, or making it more winding; or by stopping the bottom with rows of planks, stakes, or piles, which break the current. It is also required that the foundation of bridges be laid at that season of the year when the waters are lowest; and if the ground is rocky, hard gravel, or stony, the first stones of the foundation may be laid on the surface; but if the soil is soft sand, it will be necessary to dig till a firm bottom is found.

Bridges should rather be of few and large arches, than of many smaller ones, if the height and situation will possibly allow of it; for this will leave more free passage for the water and navigation, and be a great saving in materials and labour; as there will be fewer piers and centres, and the arches, &c. will require less materials; a remarkable instance of which appears in the difference between the bridges of Westminster and Blackfriars, the expense of the former being more than double the latter.

For the proper execution of a bridge, and making an estimate of the expense, &c. it is necessary to have three plans, three sections, and an elevation. The three plans are so many horizontal sections, *viz.* first a plan of the foundation under the piers, with the particular circumstances attending it, whether of gratings, planks, piles, &c. the second is the plan of the piers and arches; and the third is the plan of the superstructure, with the paved road and banquet. The three sections are vertical ones; the first of them a longitudinal section from end to end of the bridge, and through the middle of the breadth; the second, a transverse one, or across it, and through the summit of an arch; and the third also across, but taken upon a pier. The elevation is an orthographic projection of one side or face of the bridge, or its appearance as viewed at a distance, showing the exterior aspect of the materials, with the manner in which they are disposed, &c.

For the figure of the arches, some prefer the semicircle, though perhaps without knowing any good reason why; others the elliptical form, as having many advantages over the semicircular; and some talk of the catenarian arch, though its pretended advantages are only chimerical; but the arch of equilibration is the only perfect one, so as to be equally strong in every part. See ARCH of EQUILIBRATION. The piers are of different thickness, according to the figure, span, and height of the arches.

With the Romans, the repairing and building of bridges were committed to the priests, thence named pontifices; next to the censors, or curators of the roads; but at last the emperors took the care of the bridges into their own hands. Thus, the Pons Janiculensis was built of marble by Antoninus Pius; the Pons Cestius was restored by Gordian; and Arian built a new one which was called after his own name. In the middle age, bridge building was counted among the acts of religion; and, toward the end of the 12th century, St. Benezet founded a regular order of hospitallers, under the name of pontifices, or bridge builders, whose office was to assist travellers, by making bridges, settling ferries, and receiving strangers into hospitals, or houses, built on the banks of rivers.

Among the bridges of antiquity, that built by Trajan over the Danube, it is allowed, is the most magnificent. It was demolished by his next successor Adrian, and the ruins are still to be seen in the middle of the Danube, near the city Warhel, in Hungary. It had 20 piers, of square stone, each of which was 150 feet high above the foundation, 60 feet in breadth, and 170 feet distant from one another, which is the span or width of the arches; so that the whole length of the bridge was more than 1530 yards, or nearly one mile.

In France, the Pont de Garde is a very bold structure; the piers being only 13 feet thick, yet serving to support an immense weight of a tripliicate arcade, and joining two mountains. It consists of three bridges, one over another; the uppermost of which is an aqueduct.

The bridge of Avignon, which was finished in the year 1188, consists of 18 arches, and measures 1340 paces, or about one thousand yards in length.

The famous bridge at Venice, called the Rialto, passes for a masterpiece of art, consisting of only one very flat and bold arch, near a hundred feet span, and only 23 feet high above the water: it was built in 1591. Poulet also mentions a bridge of a single arch, in the city of Munster in Bothnia, much bolder than that of the Rialto at Venice. Yet these are nothing to a bridge in China, built from one mountain to another, consisting of a single arch, 400 cubits long and 500 cubits high, whence it is called the flying bridge; and a figure of it is given in the Philosophical Transactions. Kircher also speaks of a bridge in the same country three hundred and sixty perches long without any arch, but supported by three hundred pillars.

There are many bridges of considerable note in our own country. The triangular bridge at Crowland in Lincolnshire, it is said, is the most ancient Gothic structure remaining entire in the kingdom; and was erected about the year 860.

London bridge is on the old Gothic structure, with twenty small locks or arches, each of only twenty feet wide; but there are now only eighteen open, two having been thrown into one in the centre, and another next one side is concealed or covered up. It is nine hundred feet long, sixty high, and seventy-four wide; the piers are from twenty-five to thirty-four feet broad, with starlings projecting at the ends; so that the great water way, when the tide is above the starlings, was 450 feet, scarcely half the breadth of the river; and below the starlings the water way was reduced to one hundred and ninety-four feet, before the opening of the centre.

London bridge was first built with timber, between the years 993 and 1016; and it was repaired or rather new built with timber, 1163. The stone bridge was begun in 1176, and finished in 1209. It is probable there were no houses on this bridge for upward of 200 years; since we read of a tilt and tournament held on it in 1395. Houses it seems were erected on it afterward; but being found of great inconvenience and nuisance, they were removed in 1758, and the avenues to it enlarged, and the whole made more commodious; the two middle arches were then thrown into one, by removing the pier from between them; the whole repairs amounting to above 80,000*l.*

The longest bridge in England is that over the Trent at Burton, built in the 12th century, of squared freestone, and is strong and lofty; it contains thirty-four arches, and the whole length is 1545 feet. But this falls far short of the wooden bridge over the Drave, which according to Dr. Brown, is at least five miles long.

But one of the most singular bridges in Europe, is that built over the Taaf in Glamorganshire, by William

Edward, a poor country mason, in the year 1756. This remarkable bridge consists of only one stupendous arch, which, though only eight feet broad, and thirty-five feet high, is no less than one hundred and forty feet span, being part of a circle of one hundred and seventy-five feet diameter.

Of modern bridges, perhaps the two finest in Europe, are the Westminster and Blackfriars bridges over the river Thames at London. The former is 1220 feet long, and 44 feet wide, having a commodious broad footpath on each side for passengers. It consists of thirteen large, and two small arches, all semicircular, with fourteen intermediate piers. The arches all spring from about two feet above low water mark; the middle arch is seventy-six feet wide, and the others on each side decrease always by four feet at a time. The two middle piers are each seventeen feet thick at the springing of the arches; and the others decrease equally on each side by one foot at a time; every pier terminating with a salient right angle against either stream. This bridge is built of the best materials, and in a neat and elegant taste, but the arches are too small for the quantity of masonry contained in it. This bridge was begun in 1738, and opened in 1750; and the whole sum of money granted and paid for the erection of this bridge, with the purchase of houses to take down, and widening the avenues, &c. amounted to 389,500*l*.

Blackfriars bridge, nearly opposite the centre of the city of London, was begun in 1710, and was completed in ten years and three quarters; and is an exceeding light and elegant structure; but the materials unfortunately do not seem to be the best, as many of the arch stones are decaying. It consists of nine large, elegant, elliptical arches; the centre arch being one hundred feet wide, and those on each side decreasing in a regular gradation, to the smallest, at each extremity, which is seventy feet wide. The breadth of the bridge is forty-two feet, and the length from wharf to wharf nine hundred and ninety-five. The upper surface is a portion of a very large circle, which forms an elegant figure, and is of convenient passage over it. The whole expense was 150,840*l*.

Bridges, *iron*, are the exclusive invention of British artists. The first that has been erected on a large scale is that over the river Severn, at Coalbrook Dale, in Shropshire. This bridge is composed of five ribs, and each rib of three concentric arcs connected together by radiating pieces. The interior arc forms a complete semicircle; but the others extend only to the cills under the road way. These arcs pass through an upright frame of iron at each end, which serves as a guide; and the small space in the haunches between the frames and the outer arc is filled with a ring of about seven feet diameter. Upon the top of the ribs are laid cast iron plates, which sustain the road way. The arch of this bridge is one hundred feet six inches in span; the interior ring is cast in two pieces, each piece being about seventy feet in length. It was constructed in the year 1779, by Mr. Abraham Darby, iron master at Coalbrook Dale, and must be considered as a very bold effort in the first instance of adopting a new material. The total weight of the metal is 378½ tons. See Plate XXII.

The second iron bridge, of which the particulars have come to our knowledge, was that designed by Mr. Thomas Paine, author of many political works. It was constructed by Mess'rs. Walkers at Rotherham, and was brought to London, and set up in a bowling green at Paddington, where it was exhibited for some time. After which it was intended to have been sent to America; but Mr. Paine not being able to defray the expense, the manufacturers took it back, and the malleable iron was afterward worked up in the construction of the bridge at Wearmouth.

The third iron bridge of importance erected in Great Britain, was that over the river Wear, at Bishop Wearmouth, near Sunderland, the chief projector of which was Rowland Burdon, Esq. M. P. This bridge consists of a single arch, whose span is 236 feet; and as the springing stones at each side project two feet, the whole opening is 240 feet. The arch is a segment of a circle of about 444 feet diameter; its versed sine is thirty-four feet, and the whole height from low water about one hundred feet, admitting vessels of from two to three hundred tons burthen to pass under, without striking their masts. A series of one hundred and five blocks form a rib, and six of these ribs compose the breadth of the bridge. The spandrels, or the spaces between the arch and the road way, are filled up by cast iron circles, which touch the outer circumference of the arch, and at the same time support the road way, thus gradually diminishing from the abutments toward the centre of the bridge. There are also diagonal iron bars, which are laid on the tops of the ribs, and extended to the abutments to keep the ribs from twisting. The superstructure is a strong frame of timber planked over to support the carriage road, which is composed of marl, limestone, and gravel, with a cement of tar and chalk immediately upon the planks to preserve them. The whole width of the bridge is thirty-two feet. The abutments are masses of almost solid masonry, twenty-four feet in thickness, forty-two in breadth at bottom, and thirty-seven at top. The south pier is founded on the solid rock, and rises from about twenty-two feet above the bed of the river. On the north side the ground was not so favourable, so that it was necessary to carry the foundation ten feet below the bed. The weight of the iron in this extraordinary fabric amounts to 260 tons; 46 of these are malleable, and 214 cast. The entire expense was 27,000*l*.

The splendid example of the bridge at Wearmouth gave an impulse to public taste, and caused an emulation among artists, which has produced many examples and more projects of iron bridges. The Coalbrook Dale Company have constructed several, among which is a very neat one over the river Parrot at Bridgewater. Mr. Wilson, the engineer employed by Mr. Burdon, has also built several: and has lately finished a very elegant one over the river Thames, at Staines, which is by far the most complete in design, as well as the best executed, of any that has hitherto been erected. This bridge consists of a single arch, 181 feet in span, and 16 feet six inches in rise, being a segment of a circle of 480 feet. The blocks of which the ribs are composed, are similar to those in the Wearmouth bridge, except that these have only two concentric arcs instead of three, as at the latter. The arcs are cast hollow, and the blocks connected by means of dowels and keys; thus obviating the great defect observed at Wearmouth, of having so much hammered iron exposed to the action of the air. Four ribs form the width of the

arch, which are connected together by cross frames. The spandrels are filled with circles which support a covering of iron plates an inch thick: on this is laid the road way twenty-seven feet wide. Two hundred and seventy tons are the weight of the iron employed in the bridge, and three hundred and thirty of the road way.

BRIEF, any writ in writing issued out of any of the king's courts of record at Westminster, whereby any thing is commanded to be done in order to justice.

Briefs for collecting charity are to be read in all churches and chapels within two months after receipt thereof, and the sums thereby collected shall be paid over to the undertaker of briefs, within six months after the delivery of the briefs under penalty of 20*l.*

Brief also signifies an abridgment of the client's case made out for the instruction of counsel, on a trial at law, which is to be fully but briefly stated.

Briefs *apostolical*, letters which the pope despatches to princes, or other magistrates, relating to any public affair. These briefs are distinguished from bulls, the latter being more ample and always written on parchment and sealed with lead or green wax, whereas briefs are very concise, written on paper, sealed with red wax, and with the seal of the fisherman, or St. Peter in a boat.

BRIGADE, in the military art, a party or division of a body of soldiers, whether horse or foot, under the command of a brigadier. An army is divided into brigades of horse and brigades of foot: a brigade of horse is a body of eight or ten squadrons; a brigade of foot consists of four, five, or six battalions.

Brigade-major is an officer appointed by the brigadier, to assist him in the management and ordering of his brigade.

BRIADIER is the general officer who has the command of a brigade. The eldest colonels are generally advanced to this post. He that is upon duty is brigadier of the day. They march at the head of their own brigades, and are allowed a serjeant and ten men of their own brigade for their guard.

BRIGANTINE, a coat of mail, a kind of ancient defensive armour, consisting of thin jointed scales of plate, pliant and easy to the body.

BRIMSTONE. See Sulphur. Brimstone medals, figures, &c. may be cast from a composition consisting of equal weights of sulphur and vermilion melted together, and when cleared it may be cast in a mould smeared with oil. If it should change to a yellowish hue, wet it with aquafortis and it will have the appearance of fine coral.

BRINE PANS, the pits in which salt water is retained, and suffered to stand, to bear the action of the sun, by which it is converted into salt.

Brine pit, the salt spring from which the water to be boiled into salt is taken. There are many of these springs in this country; that at Nantwich, in Cheshire, is said to be sufficient to yield salt for the whole kingdom.

BRING to, in naval affairs, to check or retard the velocity, or rate of sailing of a ship, by arranging the sails in such a manner, that they shall counteract each other, and thus prevent her either from advancing ahead, or getting sternway.

BRINING of grain; the practice of immersing it in some sort of liquor or pickle to prevent the smut, or other diseases, and also to guard it from the ravages of insects. Mr. Arthur Young, in his Farmer's Calendar, says, that from various experiments it appears that steeping wheat from twelve to twenty-four hours in a lye of wood ashes, in lime water, and in a solution of arsenic, gave clean crops from extremely smutty seed.

Brining of hay, the blending of salt with hay in the operation of stacking, to preserve and render it palatable. This practice is useful in rainy seasons, and it prevails chiefly in America.

BRISTLE, a thick glossy kind of hair, with which the swine kind are more especially covered. They are hard, transparent, horny substances, of a prismatical figure, without any appearance of cavities or pores in them. Cat's bristles, or whiskers, have a solid pith in the middle. Hog's bristles constitute an important article of exportation in Russia; those imported into this country pay a heavy duty.

Bristle dice, a sort of false dice, furnished with a piece of hog's bristle stuck in the corners, to prevent them from falling on certain sides, and to make them run high or low at pleasure.

BRISTOL water. See Mineral Waters.

BRIZA, in botany, quaking grass: a genus of the digynia order, and triandria class of plants; and in the natural method ranking under the 4th order, gramina. The calyx is two valved, and multiflorous; the spicula bifarious, with the small valves heart shaped and blunt, and the inner one small in proportion to the rest. There are six species of briza: two of which are natives of Britain, *viz.*

1. Briza media, the middle quaking grass, and
2. Briza minor, the small quaking grass. Both grow in pasture grounds. The briza maxima is a native of the south of Europe, and is a very ornamental plant in gardens.

BROCADE, a stuff of gold, silver, or silk, raised and enriched with flowers, foliages, and other ornaments, according to the fancy of the merchants or manufacturers. Formerly the word signified only a stuff, woven all of gold, both in the warp and in the woof, or all of silver, or of both mixed together: thence it passed to those of stuffs in which there was silk mixed, to raise and terminate the gold or silver flowers: but now all stuffs, even those of silk alone, whether they are grograms of Tours or of Naples, satins, and even taffeties or lutestrings, if they are but adorned and worked with some flowers, or other figures, are called brocades.

BROKER, a name given to persons of several and very different professions, the chief of which are exchange brokers, stock brokers, pawn brokers, and brokers simply so called, who sell household furniture, and second hand apparel.

Brokers, exchange, are a kind of agents, or negotiators, who contrive, propose, and conclude bargains between merchants, and between merchants and tradesmen, in matters of bills of exchange, or merchandise, for which they have so much commission. These, by the statute of 8 and 9 William III. are to be licensed in London by the lord mayor, who administers to them an oath, and takes bond for the faithful execution of their offices. If any person shall act as broker, without being thus licensed and admitted, he shall forfeit the sum of 500*l.* and persons employing him 5*l.* and brokers are to register contracts, &c. under the like penalty: also brokers shall not deal for themselves, on pain of forfeiting 200*l.* They

are to carry about with them a silver medal, having the king's arms, and the arms of the city, and pay 40*s.* a year to the chamber of the city.

The exchange brokers make it their business to know the alteration of the course of exchange, to inform merchants how it goes, and to give notice to those who have money to receive, or pay, beyond sea; they are the proper persons for negotiating the exchange, and when the matter is accomplished, that is, when the money for the bill is paid, and the bill delivered, they have for brokerage 2*s.* for 100*l.* sterling.

Brokers, stock, are those employed to buy and sell shares in the joint stock of a company, or in the public funds. The negotiations of these brokers are regulated by certain acts of parliament, which among other things enact, that contracts in the nature of wagers, incur a penalty of 500*l.* and by the sale of stock, of which the seller is not possessed, and which he does not transfer, a forfeit of 100*l.* and contracts for the sale of any stock, of which the contractors are not actually possessed, or to which they are not entitled, are void, and the parties agreeing to sell, &c. incur a penalty of 500*l.* and that brokers keep a book in which all contracts, &c. shall be regularly entered.

Brokers, *pawn*, are persons who keep shops, and let out money, to necessitous people, upon pledges, on interest. This trade is regulated by statutes, which prevent the demand of exorbitant interest; which prohibit pawn brokers from purchasing goods in their custody, and from lending money to any person appearing to be under twelve years of age, or intoxicated. Pawn brokers are to place in their shops, a table of rates allowed by act of parliament; they are subject also to divers other restrictions, evidently intended as a security to the poor, whose exigencies or misfortunes oblige them to part with their property, to satisfy their most pressing wants.

BROMELIA, the pine apple: See Plate XXIII. Nat. Hist. fig. 64, a genus of the monogynia order, and hexandria class of plants; and in the natural method ranking under the tenth order, coronariæ. The essential character is, calyx, trifid, superior: corolla with nectareous scales at the base of each berry, three celled. There are nine species, of which the following are the most remarkable:

1. Bromelia ananas, with leaves very like some sorts of aloes, but not so thick and succulent, which are strongly armed with black spines. From the centre of the plant arises the flower stalk, which is near three feet high; the lower part is garnished with entire leaves, placed alternately at every joint. The upper part is garnished with flowers set in a loose spike or thyrse quite round: these are succeeded by oval seed vessels, having a longitudinal partition, in the centre of which are fastened smooth cylindrical seeds. Of this there are six varieties.

2. Bromelia lingulata, with obtuse, sawed, and prickly leaves.

3. Bromelia nudicaulis, with the lower leaves indented and prickly. The leaves of this species are shorter than those of the ananas. They are sharply sawed on their edges, and of a deep green colour. The flower stem arises from the centre of the plant, which divides upward into several branches; the upper part of these are garnished with spikes of flowers, which come out alternately from the sides of the branches, each having a narrow entire leaf just below it, which are longer than the spike. The flowers are placed very close on the spikes: and when they decay, the empalement turns to an oval pointed seed vessel, enclosing seeds of the same shape with the other.

The plants of the pine apple are propagated by planting the crowns which grow on the fruit, or the suckers which are produced either from the sides of the plants or under the fruit. The suckers and crowns must be laid to dry in a warm place for four or five days, or more; for if they are immediately planted they will rot. The certain rule of judging when they are fit to plant, is by observing if the bottom is healed over and become hard. In summer, they must be frequently watered; but not with large quantities at a time; and the moisture should not be detained in the pots by the holes being stopped, for that will soon destroy the plants. If the season is warm, they should be watered twice a week; but in a cool season, once a week will be sufficient; and in summer they should once a week be watered gently all over the leaves; which will greatly promote their growth. During the winter, they will not require to be watered oftener than once a week, according as the earth in the pots seems to dry. Plants beginning to show their fruit should never be shifted; for if they are removed after the fruit appears, it stops the growth, and thereby causes the fruit to be smaller, and retards its ripening, so that it will be October or November before the fruit is ripe; therefore the plants should be kept in a vigorous growing state from the first appearance of the fruit, as upon this depends the goodness and the size of it. After cutting off the fruit from the plant intended to be propagated, the leaves should be trimmed, and the pots plunged again into a moderate hot bed, observing to refresh them frequently with water, which will make them put out suckers in plenty; so that one may be soon supplied with plants enough of any of the kinds, who will but observe to keep the plants in health. The most dangerous thing that can happen to these plants is their being attacked by small white insects, which appear at first like a white mildew, but soon after have the appearance of lice: these attack both root and leaves at the same time; and if they are not soon destroyed, will spread over a whole stove in a short time, and in a few weeks entirely stop the growth of the plants by sucking out the nutritious juice, so that the leaves will appear yellow and sickly, and have a number of yellow transparent spots all over them. These insects, after they are fully grown, appear like bugs, adhering so closely to the leaves as not to be easily washed off, and seem to have no local motion. They were originally brought from America upon the plants imported from thence. The only method yet discovered of destroying them, is by frequently washing the leaves, branches, and stems, of such plants as they attack, with water in which there has been a strong infusion of tobacco stalks. But this method cannot be practised on the ananas plants, because the insects fasten themselves so low between the leaves, that it is impossible to come at them with a sponge to wash them off; so that although they seem to be all cleared off, they are soon succeeded by a fresh supply from below, and the roots are also equally infected at the same time. Therefore, whenever they appear on the plants, the

safest method is to take the plants out of the pots, and clear the earth from the roots; then put them into a tub, filled with water in which there has been a strong infusion of tobacco stalks; and lay some sticks across to keep them immersed in the water, wherein they should remain twenty-four hours; then take them out, and with a sponge wash off all the insects from the leaves and roots, and wash the plants in a tub of fresh water. This is the most effectual way to clear them from the insects. After this, you should put them in fresh earth; and, having stirred up the bark bed, and added some new tan to give a fresh heat to the bed, the pots should be plunged again, observing to water them all over the leaves, and this should be repeated once a week during summer; for these insects always multiply much faster where the plants are kept dry, than when they are sometimes sprinkled over with water, and kept in a growing state.

Of late, some very considerable improvements have been made in this article. The leaves of the oak have been substituted for the more expensive bark; and the pines treated with them are found to thrive as well, and to produce as good fruit as the others. But the most considerable improvement is that mentioned in the 67th volume of the Philosophical Transactions, where the following method is shown by William Bastard, esq. of Devonshire, of raising these fruits in water. "The way in which I treat them," says he, "is as follows: I place a shelf near the highest part of the back wall, that the pine plants may stand without absolutely touching the glass, but as near as it can be; on this shelf I place pans full of water, about seven or eight inches deep; and in these pans I put the pine apple plants, growing in the same pots of earth as they are generally planted in, to be plunged into the bark bed in the common way; that is, I put the pot of earth, with the pine plant in it, in the pan full of water, and as the water decreases I constantly fill up the pan. I place either plants in fruit, or young plants as soon as they are well rooted, in these pans of water, and find they thrive equally well: the fruit reared this way is always much larger as well as better flavoured, than when ripened in the bark bed. I have more than once put only the plants themselves without any earth, I mean after they had roots, into these pans of water, with only water sufficient to keep the roots always covered, and found them flourish beyond expectation. In my house, the shelf I mention is supported by irons from the top, and there is an intervening space of about ten inches between the back wall and the shelf. A neighbour of mine has placed a leaden cistern upon the top of the back flue, (in which, as it is in contact with the flue, the water is always warm when there is fire in the house,) and finds his fruit excellent and large. My shelf does not touch the back flue, but is about a foot above it; and consequently only warmed by the air in the house. Both these methods do well. The way I account for this success is, that the warm air always ascending to the part where this shelf is placed, as being the highest part of the house, keeps it much hotter than in any other part. The temperature at that place is, I believe, seldom less than what is indicated by 73° of Fahrenheit's thermometer, and when the sun shines it is often above 100°; the water the plants grow in, seems to enable them to bear the greatest heat, if sufficient air is allowed; and I often see the roots of the plants growing out of the holes in the bottom of the pot of earth, and shooting vigorously in the water."

BROMUS, BROOM GRASS, in botany: a genus of the digynia order, and triandria class of plants; and, in the natural method, ranking under the 4th order, gramina. The calyx is bivalved, having a partial spike, oblong and round, opposite grains, with an awn below the point of each outer valve. There are 25 species, of which seven are natives of Britain, *viz.*

1. Bromus arvensis, common broom grass;
2. Bromus ciliatus, wall broom grass;
3. Bromus giganteus, tall broom grass;
4. Bromus pinnatus, spiked broom grass;
5. Bromus ramosus, wood broom grass;
6. Bromus secalinus, field broom grass;
7. Bromus sterilis, barren broom grass.

BRONCHIA. See ANATOMY.

BRONCHOCELE, in surgery, a tumour rising in the fore part of the neck. This disorder with us is frequently called a Derbyshire neck, on account of the inhabitants of that county being much subject to it; probably for the same reasons that the inhabitants about the vallies of the Alps, and other mountainous countries, are so much affected with it. The most common situation of this swelling is the sides of the thyroid gland, and in many cases it seems to consist of a general enlargement of that organ. This disease is known to predominate most in countries affected by the humidity of the atmosphere, joined with excessive heat: it increases in the spring time, and diminishes in the autumn; it is less prevalent in cold and dry seasons, than in those that are damp, and moderately warm; it has been asserted that its progress, wherever it is endemial, is in exact proportion to the degree of moisture indicated by the hydrometer.

BRONCHOTOMY, in surgery, an incision made in the aspera arteria, or windpipe, which is necessary in many cases, and especially in a violent quinsy, to prevent suffocation from the great inflammation or tumour of the parts. It is also called laryngotomy and tracheotomy. See SURGERY.

BRONCHUS, in anatomy, the lower part of the aspera arteria, dividing in bronchiæ, or branches. In this sense it stands contradistinguished from the larynx. The name is frequently extended to the whole aspera arteria or trachea.

BRONTIÆ, thunder stones, a kind of hemispherical stones divided by zones. The word is Greek, signifying thunder, in reference to the popular tradition, that this species of stones fall in thunder showers.

BRONZE, a compound metal, composed of from 6 to 12 parts of tin combined with 100 parts of copper. This alloy is heavier than copper, and possesses more tenacity; it is more fusible, and less liable to be altered by exposure to the air. This composition is used for cannon as well as for medals.

BRONZES, a name given by antiquarians to figures either of men or beasts, to urns, and, in general, to every piece of sculpture which the ancients made of that metal. We likewise give the name of bronzes to statues and busts cast of bronze, whether these pieces are copies of antiques, or original subjects.

The method of casting bronzes is as follows: The figure to be cast, must have a mould made on it with a mixture of one part of plaster of Paris, and two parts of brick dust. In the joints little channels should be cut from different parts of the internal hollow, tending upward, to give vent to the air which the metal will force out, as it runs into the mould. When the mould is made, a thin layer of clay should be spread over the inside, the same thickness the bronze is intended to be: then the mould must be closed, and the hollow within the layer of clay filled with two thirds of brick dust, and one third of plaster mixed with water. This will make the core; and if the figure to be cast should be large, strong bars of iron forming a skeleton of support for the metal figure must be laid in the mould, and round this the core must be cast; when this is done, the mould must be opened again, and round this the core of clay taken out; the mould and core must be thoroughly dried, to prevent any accident with the cast. The core is then to be laid in the mould, and supported by short bars of bronze which run through the mould into the core. The mould is now to be laid in a situation for casting; a channel must be continued sufficiently sloping from the reservoir of metal to the mouth of the mould for the liquid bronze to run easily. The form of the furnace, and the manner of running the metal, are the same as those employed in the bell foundery.

BRONZING, the art of varnishing wood, plaster, ivory, &c. so as to give them the colour of bronze. There are two sorts of composition used for this purpose, the red and the yellow; the latter is made of the finest copper dust, and to the former is added a small quantity of red ochre, well pulverized. Both are applied with varnish, and the work is dried over a chafingdish as soon as bronzed.

BROOM, in botany. See SPARTIUM, and GENISTA.

BROOM FLOWER, *ordre de la geniste*, an order instituted by St. Louis, king of France, to show the esteem which he had for the queen his wife; and who, the evening before his queen's coronation, received this order himself.

The collar of this order was a gold chain of broom flowers, interlaced with fleur-de-lis: the inscription, "exaltat humiles," the founder accounting the broom the symbol of humility.

BROSÆA, in botany, a genus of plants, of the order monogynia, and pentandria class. The characters are these: the cup is a one leaved perianthium, five segments; the flower is monopetalous, of the shape of a truncated cone. The fruit is a roundish capsule, divided into five cells, and opening at the sides, discharges a great number of seeds. There is one species, a native of South America.

BROTHERHOOD *of God*, a Christian denomination associated together for restraining and abolishing the right and exercise of private war. This sect was founded in the 12th century by a carpenter at Guienne, who pretended to have had divine communication with Jesus Christ and the Virgin Mary. He was received as an inspired messenger of God. Many prelates and barons assembled at Puy, and took an oath, not only to make peace with all their own enemies, but to attack such as refused to lay down their arms, and to be reconciled to their enemies.

BROWALLIA, in botany, a genus of the angiospermia order, in the didynamia class of plants. The essential character is, calyx five toothed: corolla five cleft, equal spreading with the navel closed: anthers, two larger: capsule one celled. There are two species, both annuals, *viz.*

1. Browallia demissa, with a single flower upon each footstalk. The seeds were sent to Mr. Miller, from Panama. The flowers are of a light blue colour, sometimes inclining to a purple or red; and there are often three colours of flowers on the same plant. They flower in July, August, and September.

2. Browallia elata, with one or many flowers on each footstalk, is a native of Peru. The stalk appears somewhat shrubby; the footstalks have sometimes one flower, others with three, and others with five, of a deep violet colour. As both species of browallia are annual plants, they must be raised from seeds, which are to be sown on a hot bed; but they may be transplanted in June, into the borders of the flower garden; where, if the weather proves warm, they will flower and perfect seeds; but lest these should fail, there should be a plant or two kept in the greenhouse to secure seeds.

BROWN, among dyers, painters, &c. a dusky colour, inclining toward redness. Of this colour there are various shades or degrees, distinguished by different appellations: for instance, Spanish brown, a sad brown, a tawny brown, the London brown, a clove brown, &c.

Spanish brown is a dark dull red, of a horse flesh colour. It is an earth, and is of great use among painters, being generally used as the first and priming colour that they lay upon any kind of timber work in house painting. That which is of the deepest colour, and freest from stones, is the best. Though this is of a dirty brown colour, yet it is not much used to colour any garment, unless it be an old man's gown; but to shadow vermilion, or to lay upon any dark ground behind a picture, or to shadow yellow berries in the darkest places, when lake is wanted, &c. It is best and brightest when burnt in the fire till it is red hot, although, to colour a hare, horse, dog, or the like, it should not be burnt; but, for other uses, it is best when it is burnt, as for instance, for colouring wood, posts, bodies of trees, or any thing else of wood, or any dark ground of a picture.

The method of dyeing browns is by plunging the cloth in a boiling bath of red wood ground and nut galls bruised; and when it has boiled for two hours and a half, and has been cooled and aired, it is plunged again in the same bath, to which a proportionable quantity of copperas must first be added. The more dull you would have the brown, the more copperas must be put in.

BROWNISTS, in church history, a religious sect, which sprung up in England toward the end of the 16th century. Their leader was one Robert Brown, born at Northampton. They separated from the established church, on account of its discipline and form of government. They equally disliked episcopacy and presbyterianism. They condemned the solemn celebration of marriages in churches, maintaining, that matrimony being a political contract, the confirmation of it ought to proceed from the civil magistrate. They rejected all forms of prayer, and held that the Lord's prayer was not to be recited as a prayer; being given only as a model, upon which to form our prayers.

BRUCEA, in botany, a genus of the tetrandria order, and dioecia class of plants. The essential character is, calyx four leaved: corolla, four petaled: fem. perri. four one seeded. There is one species, a shrub of Abyssinia. It is a simple bitter, leaving in the throat something of roughness resembling ipecacuanha.

BRUCHUS, a genus of coleopterous insects, with filiform antennæ, equal filiform feelers, and acuminated lip. The species of this genus are in all twenty-five.

BRUISER, the name of a concave tool used for grinding and polishing the specula of telescopes. It is made of brass about a quarter of an inch thick, and hammered as near the gauge as possible. It is tinned on the convex side, and made equally broad at bottom and top. By this instrument the speculum is prepared for the hands of the polisher.

BRUNSFELIA, in botany, a genus of the monogynia order, and pentandria class of plants. The corolla is funnel shaped, and very long; and the fruit an unilocular polyspermous berry. There are two species.

Brunsfelia Americana, rises six or eight feet high, has a woody branching rough stem, with oblong entire leaves on footstalks, and large whitish flowers by threes or fours at the ends of the branches, succeeded by round saffron coloured soft fruit. It may be raised from seeds sown in pots in the spring, and plunged in a bark bed. It may also be propagated by cuttings planted in pots in the same season, plunging them also in a bark bed or other hot bed under glasses. The plants must always remain in the stove. 2d, B. undulate. Both natives of Jamaica.

BRUNIA, in botany, a genus of the monogynia order, and pentandria class of plants. The flowers are aggregate or clustered; the filaments inserted into the heels of the petals; the stigma is bifid, the seeds are solitary, and the capsule is bilocular. There are eight species, natives of the Cape.

BRUNICHIA cirrhosa, in botany, a plant of the class decandria, order digynia. The cal. 5 parted, cor. none, capsule 1 sperm. 3 sided. It is a native of Carolina and Missisippi. (*a*)

BRUNONIAN *system*, the system of medicine discovered by the late Dr. Brown, and explained at large in his Elements of Medicine. It might appear proper to give an account of this doctrine under the general article MEDICINE; but the new system differs so widely from all former systems of that science, that we think it more consistent with propriety to delineate it under its own proper title. The following will give a sufficient view of the outlines of this doctrine to such as are unacquainted with it; and for its minutiæ we must refer to the doctor's own works, and those of Dr. Beddoes, Dr. Jones, &c.

BRUNONIAN *system, account of*. The human body, particularly the system of solids it consists of, is a form of living matter, whose characteristics are sensation and motion. The capability of being affected by external powers is termed *excitability;* the agents *stimuli*, or exciting powers; the result *excitement*. Without this property, excitability, the body would be dead inert matter: by this property it becomes living matter; by this property, called into action by the exciting powers, it becomes a living system. While the *stimuli* act on the *excitability* with a sufficient degree of power, then is the pleasant sensation of health: when they raise the excitement above this point, or depress it below it, disease takes place: when the stimuli cease to act, or the system to feel their power, death ensues. *Excitability* is a property of living matter, peculiar and inherent, but it is a property which Dr. Brown did not pretend to explain. He left it as sir Isaac Newton did his *attraction*, as a property not to be investigated. Of this energy or power there is assigned to every living system, at the commencement of life, a certain quantity or proportion; but its quantity differs in each, and in the same body it is found to change; for the excitability, according to circumstances, may be "abundant, increased, accumulated, superfluous, exhausted, consumed," &c. The *stimuli*, or exciting powers, are of two classes, external and internal. The external stimuli are heat, light, sound, air, and motion; food, drink, medicines, and whatever else is taken into the body, not excepting poisons and contagions. The internal are the functions of the body, the blood, the secretions, muscular exertion, and finally the powers of the mind; as sensation, passion, and thought. *Excitement* is life; the natural movements of the machine, and the functions resulting from these, as sensation, reflection, and voluntary motion, as they immediately flow from the exciting powers, are vigorous when they are strong, languid when they are weak, and cease when they are taken away entirely. Thus our body is continually moved by external agents, and life is a *forced state*. Our weak frame has an unceasing tendency to dissolution, which is opposed only by the incessant application of *exciting powers*, which are the sources of life, and which, being partially or completely withdrawn, are immediately followed by disease or death. It is also a principle of this doctrine, that "all stimuli by acting on the excitability exhaust it." Thus the stimuli of food, air, motion, passion, and thought, have supported the body through the labours of the day: they have supported the functions by acting on the excitability; in the evening it is exhausted by their continued operation; they have no longer the same power; the functions fail; we sink into rest, and continue in sleep, unaffected by the stimuli, renewing by sleep that excitability which had been exhausted by the labours or by the pleasures of the day; we rise with restored excitability; we feel a new power of excitement in every object around us; we are refreshed in the morning, and languid at night, and our whole life is an alternation of motion and rest, of action and sleep, of apathy and pleasure, of wasting our excitability by day in labour or enjoyment, and of recruiting it by night by the abstraction of all stimulant powers. The same philosophy extends to the duration of life: in childhood excitability is abundant in *quantity*, as being little exhausted; but it is low in power, because the tender stamina and accumulated excitability of children can neither suffer nor support high excitement. Their excitability is so abundant, that they are easily supported by weak diet and low exciting powers, and therefore most of their diseases are diseases of weakness. In youth and manhood the excitability is yet entire, the stamina are strong, the powerful stimuli are applied, and high passions prevail: these are the periods of vigour, and the era of inflammatory disease. In old age the stamina are worn, the excitability is exhausted, the common stimuli have lost their

power, and the system begins to decline; we have weakness of body, imbecility of mind, and asthenic diseases. We may last of all have recourse to more generous diet, and raise the stimulant powers by substituting wine to water or brandy to wine; thus perhaps excitement may be awhile supported, and life prolonged; but in a few years these also fail. This doctrine further teaches, that our body is never moved but by exciting powers. None but stimuli affect our system. That there are direct sedatives in nature, is esteemed an unphilosophical and vulgar error. In stimuli there is a gradation which, being relative to the system, deceives our sense; for, as some stimuli are powerful and others weak, a low stimulus applied after a more powerful one, will stimulate less than the former, will allay the motions which the former had excited, and will, therefore, be named a sedative. Take heat as an example of this: cold is but an abstraction of heat, yet it is thought a positive existence; and cold is named a sedative and heat a stimulant power. To detect this deception of sense, plunge the right hand into water at the heat of 150°, the left into melting snow; withdraw both, and plunge them at once into water at 100°, it will prove at once stimulant and sedative; cold or sedative to the right hand, and hot or stimulant to the left. So is fasting an abstraction of the wonted stimulus of food, bleeding of the usual stimulus of blood, and so on. Health, then, is the due operation of stimuli on a well regulated excitability, producing a moderate excitement, and a pleasant sensation, moving the whole system with a just degree of power, and giving all the functions their due energy and tone. Asthenic disease, disease of debility or of weakness, is the result of stimuli applied in a low degree, or of the system less easily excited. Sthenic disease, or disease of strength, is the result of stimuli applied in too great a degree, or of a system too susceptible of excitement. The first is depression of excitement below the healthy state: it produces languid motions and functions, and requires excitement for its cure. The second is a strong state of the system, wound up to too high a degree of excitement. It is an exuberance of health and strength. It is marked by violent movements, and is cured by extraction of stimuli. Thus are all our maladies either diseases of weakness or of excessive strength; and this is the foundation of the Brunonian scale, which has for its middle point health; below that are arranged the diseases of weakness; above it the diseases of excessive strength; and in both divisions of the scale, diseases are so arranged, that the worst forms are set off at the greatest distance from the middle point, to mark them as the widest deviations from the healthy state. To illustrate still further the nature of these two forms of disease, we must observe their respective causes. Sthenia, or excessive strength, is simply the effect of many or powerful stimuli acting on the system. Asthenia is the immediate effect of withdrawing these; but asthenia is not so simple as its opposite state, for debility varies in its nature according to its various causes. 1. By abstraction of exciting powers is produced a species of debility named *direct*. 2. By long or violent application of strong exciting powers, the excitability is exhausted; both the excitement and the strength fail: this species of debility is named *indirect*. 3. When the exciting powers are withdrawn, and the direct debility produced, it is at the same time combined with a new species. By merely withdrawing the stimuli, such weakness would be produced as should be temporary only, and might be done away by restoring the usual exciting powers; but where the stimuli are withdrawn, excitability is accumulated, and when it is accumulated in an undue degree, it cannot bear the usual stimuli, and will not give out the healthy degree of excitement. Thus, direct debility caused by the absence of exciting powers, is attended with accumulation of excitability. Indirect debility, caused by superabundant stimuli, is attended with exhausted excitability. The former is most easily cured, as we have but to apply stimuli, and raise the excitement: the latter is difficultly cured; for the excitability being in some degree exhausted, the system is less susceptible, and has less excitability to operate upon for the restoration of health. The abstraction of stimuli is an immediate cause of weakness; high excitement is a state of the system which the excitability cannot long endure without being exhausted, so that stimuli themselves produce ultimate weakness. Since, therefore, high excitement is temporary only, and has but one cause, while weakness is a permanent state, and has many causes, the diseases of debility must in a very great proportion exceed in number the diseases of excessive strength; and diseases of excessive strength must ultimately end there. If 97 of 100 diseases arise from weakness, the conclusion must be of the first importance in practice. Hence it is a general principle in this system, that though there are many individual diseases, there are but two states of the system, and two general methods of cure; and though it admits the difference between local and general diseases, yet it does not allow that a local sthenic disease can exist for any time along with a general asthenic diathesis, or *vice versa*. For the cure of all those diseases which stand above the point of health, nothing more is required than withdrawing the stimuli of food, drink, heat, &c. or by evacuation, as bleeding, vomiting, and purging. For all those diseases which stand below the point of health, we use the natural stimuli of diet, beef tea, wine, heat, &c. or the less natural stimuli of the pharmacopœia, the chief of which are opium, ether, volatile alkali, musk, camphor, brandy, and other spirits. The cause of the one form of disease is the cure of the other; in the one we raise the excitement till it arrives at the point of health; in the other we depress it to the same point: having affected this by the powers of medicine, we keep it there by attention to regimen; and the great object in the Brunonian practice is to hit the point of health, neither to stop short of this object, nor to pass beyond it; for by either imprudence we may do much harm. By profusion of stimuli we may convert a disease of weakness into a disease of inflammation: by too severe an abstraction of stimuli we may run into the opposite excess, converting into a disease of weakness what was originally a disease of violent inflammation. The use of stimuli in asthenic diseases is to be regulated by the cause and state of the disease. In all diseases of indirect weakness, where excitability has been exhausted, the strength must be raised by the immediate application of the most powerful stimuli, which are to be slowly reduced in quantity or strength, till moderate or ordinary stimuli suffice for supporting the excitement of health. In all cases of direct weakness, where excitability is accumulated, the immediate application of

powerful stimuli would destroy. Weak stimuli must be first used, the superabundant excitability must be gradually wasted, and the doses very slowly increased, till we rise to the point of health.

Dr. Brown's frequent prescriptions of wine, spirits, and opium, to his patients in asthenic diseases, with his repeated recommendations of these stimuli in his lectures and writings, raised a very general prejudice against his system and practice, among those who knew nothing of either but from vague report. They alleged that, though he might cure the diseases of his patients, he would infallibly corrupt their morals, by habituating them to such dangerous medicines. From these charges Dr. Beddoes vindicates the doctrine, in the following words: p. 159. "The Brunonian system has been frequently charged with intemperance; the objection is serious, but the view already given of its principles shows it to be groundless. No writer has insisted so much upon the dependence of life upon external causes, or so strongly stated the inevitable consequences of excess; and there are no means of promoting morality upon which we can rely, except the knowledge of the true relations between man and other beings or bodies. For by this knowledge we are directly led to shun what is hurtful, and pursue what is salutary." And what stronger motive of temperance can philosophy itself inculcate than the Brunonian doctrine does, when it teaches, that every act of intemperance and excess tends to exhaust the very principle of life?

Dr. Beddoes, though he seems to be a decided Brunonian, has nevertheless, with great candour as well as judgment, pointed out a few of the imperfections of the new doctrine. 1. He observes, that, as Dr. Brown "assumes that a certain portion of excitability is originally assigned to every living system, by his very assumption he denies its continual production, subsequent diffusion, and expenditure." 2. He next objects against the doctor's "uniformity of operation in stimulants." "Heat and wine," he justly observes, "can never act in the same manner; for no person is intoxicated by heat." He adds, "Had it been once allowed by Brown that the different constituent parts of the body bear a different relation to the same agents, he must have admitted the operation of specific stimulants to an unlimited extent." On the subject of *predisposition to disease*, he observes, "that though facts have been noted, the principle lies involved in total obscurity. Brown does not purposely elude the difficulty, but his principles lead him beside it; and we may doubt whether the term *predisposition* ought in strict propriety to have appeared in his Elements; for predisposition is with him a slight disease, differing only in degree from that into which the person predisposed falls." 4. "There are several other opinions," he adds, "which, in a complete revisal of the Brunonian system, would require particular examination; such as his doctrine concerning hereditary diseases," of which Brown denies the existence, "the peculiar state of sthenic inflammation, and the nature of the passions." 5. And in a note upon Brown's preface, he styles the doctor's opinion, that 'nearly all the diseases of children depend on debility,' "a gross and dangerous error," though he admits that "thousands of them are cut off at an early period of life, and tens of thousands kept languishing in misery, by asthenic diseases, for want of the necessaries of life."

The following are among the principal objections that have been urged by the opponents of this doctrine. 1. Medicines and the other exciting powers do not act as mere stimuli only. If they did, they must have all one common nature, and differ only in degree; whereas they differ widely in their effects: one produces hilarity, as wine, &c. another coma, as opium; one poison produces phrensy, another palsy, a third convulsions, &c. If ipecacuanha operates on the stomach, jalap on the bowels, cream of tartar on the kidneys, and mercury on the salivary glands, they must have some peculiar or specific qualities superadded to their stimulant power, and the latter must be but a subordinate effect. If bark cures an intermittent fever, or mercury the venereal disease, which brandy, opium, and even ether cannot, then it is the duty of the physician to discover these secret, peculiar, and inexplicable powers, and to operate by them, without regard to their stimulant effects. 2. In opposition to the Brunonian doctrine, that there is not a direct sedative in nature, it is argued, that fixed air, and the contagion of fever, dysentery, the plague, &c. are direct sedatives, which do not stimulate in the smallest degree. 3. It has been urged, that if the new doctrine is true, there ought to be no such thing as an incurable disease. All diseases, whether above or below the point of health, ought to yield to the abstraction or application of the stimuli, as long as the excitability is not totally exhausted. 4. In short, it has been argued, that if the Brunonian system is true, there is no use for nosology or physiology; very little for chymistry or botany, as a few stimuli, with an emetic and cathartic or two, are sufficient to supply a Brunonian laboratory; and not much even for anatomy itself, that grand foundation of medical knowledge. But whatever deficiencies, imperfections, or inexplicable mysteries, may still adhere to this system, it is allowed, even by its opponents, to have contributed greatly to the improvement of medical practice; to have considerably diminished the former too frequent prescriptions of copious bleeding on almost every occasion; and to have lessened the number of evacuant doses, and increased that of corroborant medicines, in many diseases of weakness, where the opposite practice was manifestly injurious. And it is allowed to be the duty of every medical practitioner to examine it without prejudice or partiality.

BRUNSWICK GREEN, a colour used in paper hangings, and other coarse kinds of painting in water colours. It is prepared in any close vessel of wood or earthen ware, filled half full of copper filings or clippings, on which is poured a saturated solution of sal ammoniac, which together will form the muriate of copper, the ammonia being at the same time disengaged. In a few weeks almost the whole of the copper may be converted into oxyde; this being well washed, and slowly dried in the shade, is pure Brunswick green. Three parts of muriate of ammonia, or sal ammoniac, and two of copper, yield six parts of green.

BRUSH, a well known domestic utensil. The wooden part of brushes is generally of oak, which is cut to its proper size by an instrument like a large knife, fastened down to the block with a staple at one end, in such a manner that it is moveable up and down; to the other end is a handle. The wood to be cut is held in the left hand, while the knife is worked with the right. The knife is

always kept very sharp; and, by its make and mode of using, hard wood is very readily reduced to any shape and size. This wood, when cut into the proper sizes, is drilled with as many holes as is necessary, and into these the hair or bristle is put.

There are brushes of various sorts, shapes, and sizes; but the structure of them all is the same, or nearly so. When the bristles are sorted, combed, and picked, a certain portion of them is taken and tied together in the middle with string, or with fine copper or iron wire: in this double state they are fastened into the wooden stock with glue or with pitch. The ends of the hair are now to be cut off and the surface to be made even or uniform.

Common hearth brushes and hair brooms are made in a slighter way. As soon as the stock is brought to its proper shape it is drilled, the hairs doubled, and each bundle is put into the hole with some hot cement made with pitch and resin.

In some brushes, the wires are visible on the back; in others the backs are smooth, there being thin slices of wood glued over the wires.

A patent was obtained in 1804, by Mr. Thomason, for making hearth brushes, the object of which was to conceal the hair in a neat metal case, into which the hair is drawn by means of rack work.

BRYGMUS, among physicians, a grating noise made by the gnashing of teeth, a symptom common in epilepsy, and some convulsive disorders. See MEDICINE.

BRYONIA, bryony, a genus of the syngenesia order, and monoecia class of plants; in the natural method ranking under the 34th order, cucurbitaceæ. The calyx of the male is five toothed, with a quinquefid corolla, and three filaments. In the female the calyx is dentated, the corolla quadrifid, the style trifid, with a roundish many seeded berry. There are 19 species, of which the most remarkable are:

1. Bryonia Africana, African tuberous rooted bryony.

2. Bryonia alba, rough or white bryony with red flowers, a native of dry banks under hedges in many parts of Britain. The roots of this plant have by impostors been wrought into a human shape, and shown for mandrakes. Their method was to find a young thriving plant of bryony; then they opened the earth all round, being careful not to disturb the lower fibres; and being provided with such a mould as is used for making plaster figures, they fixed the mould close to the root, fastening it with wire to keep it in its proper situation; then they filled the earth about the root, leaving it to grow to the shape of the mould, which in one summer it will do; so that if done in March, by September it will have the shape. The leaves of the plant are also imposed on people for mandrake leaves, although there is no resemblance between them, nor any agreement in quality. The roots of this species are used in medicine. These are very large, sometimes as thick as a man's thigh; their smell when fresh, is strong and disagreeable; the taste nauseously bitter, acrid, and biting; the juice is so sharp, as in a little time to excoriate the skin; in drying, they lose a great part of their acrimony, and almost their whole scent. Bryony root is a strong irritating cathartic, and applied externally is said to be a powerful discutient.

3. Bryonia Bonariensis, bryony with hairy palmated leaves, divided into five parts, and obtuse segments. It is a native of warm countries; but merits cultivation on account of the pretty appearance it makes when full of fruit.

4. Bryonia Cretica, spotted bryony of Crete.

5. Bryonia racemosa, bryony with a red olive shaped fruit. It is a native of warm climates, and perennial; but the branches decay every winter.

6. Bryonia variegata, the American bryony with variegated fruit.

BRYUM, in botany, a genus of the 56th natural order, *viz.* musci, belonging to the cryptogamia class of plants. The anthera is operculated or covered with a lid, the calyptra polished, and there is a filament arising from the terminal tubercle. There are 41 species, most of them natives of England.

BUBO, or BUBOE. See SURGERY.

BUBON, Macedonian parsley: a genus of the digynia order, and pentandria class of plants; and in the natural method ranking under the 46th order, umbellatæ. The fruit is ovated, striated, and villous. There are five species, which are propagated by seeds, and require the common culture of other exotic vegetables, *viz.*

1. Bubon Galbanum or African ferula, rises with an upright stalk to the height of eight or ten feet, which at bottom is woody, having a purplish bark covered with a whitish powder that comes off when handled. The top of the stalk is terminated by an umbel of yellow flowers; which are succeeded by oblong channelled seeds, which have a thin membrane or wing on their border. When any part of the plant is broken, there issues out a little thin milk of a cream colour, which has a strong scent of galbanum.

2. Bubon gummiferum, with a mock chervil leaf, rises with a ligneous stalk about the same height, with leaves at each joint; the small leaves or lobes narrow and indented like those of bastard hemlock. The stalk is terminated by an umbel of small yellow flowers, which are succeeded by seeds like those of the former sort. The galbanum of the shops is supposed to be procured from these two species.

3. Bubon Macedonicum, sends out many leaves from the root: the lowest grow almost horizontally, spreading near the surface of the ground. In the centre of the plant arises the flower stem, which is little more than a foot high, dividing into many branches, each terminated by an umbel of white flowers, which are succeeded by oblong hairy seeds. This plant, in warm countries, is biennial; but in Britain seldom flowers till the third or fourth year; but whenever the plant flowers, it always dies.

4. Bubon rigidius, hard or rigid ferula, is a native of Sicily. It is a low perennial plant, having short, stiff, and very narrow leaves: the flower stalk rises a foot high, which is terminated by an umbel of small white flowers.

5. B. cavigattum.

BUBONOCELE, or HERNIA INGUINALIS. See SURGERY.

BUBROMA, a genus of the class and order polyadelphia dodecandria. The essential character is, calyx three leaved: petals, five arched, semibifid: anthers, on each filament, three: stigma, simple: capsule, muriate, ending in a five rayed star.

There is one species, a large tree of the West Indies, resembling the elm.

BUCCINATOR. See ANATOMY.

BUCCINUM, the TRUMPET SHELL, a genus of univalve shells, shaped, in some degree, like a horn, or other wind instrument: the belly of the shell is distended, the aperture of the mouth is large, wide, and elongated, the tail is more or less long, and the clavicle more or less exerted.

This is a very numerous genus, the principal species of which are the pomum, Plate XXIII. Nat. Hist. fig. 65. spindle shell, the mitre shell, the midas ear shell, the great triton shell, the tower of Babel shell, &c.

The shells of the buccinum kind are commonly furnished with an operculum; the animal, a limax or snail, subject to some slight difference in its form in various species. They are oviparous, and the males are said to be smaller and higher in colour than the females.

BUCCO, the Barbet, in ornithology, the name of a genus in the picæ order, distinguished by having the bill sharp edged, compressed on the sides, notched on each side near the apex, bent inward, with a long slit beneath the eyes. Nostrils covered with incumbent feathers: feet formed for climbing. There are seventeen species, and some varieties. They occur in Africa, but chiefly inhabit Asia, and the hotter parts of America. They are in general dull and stupid birds; their bill is stout, and remarkably covered with projecting bristles. Those of the ancient hemisphere are very much distinguished by the thickness and shortness of the bill; and, far from affecting the stupid gravity of the American species, they attack the smaller tribes with the boldness and intrepidity of the hawk. The principal species are as follows, *viz.*

1. The tamatia, or spotted barbet, a native of Brazil. Its length is six inches and a half, of which the tail occupies two inches; the bill is hooked, and divided into two points; the bristles or beard which covers it extends more than half its length. They feed chiefly on insects; and their flesh, though not good, is eaten by the natives.

2. The Cayanensis, or red headed barbet. This is about seven inches in length; the bill is strong, of a dark ash colour, bending a little downward at the tip; at the basis of the upper mandible are a few black bristles pointing forward over the nostrils. They are inhabitants of Cayenne, and are also met with at Guiana and St. Domingo; and, no doubt, in other hot parts of America. They feed on caterpillars, locusts, and large beetles.

3. The capensis, or collared barbet. The plumage of this bird is agreeably variegated. It is found in Guiana, but is a rare species.

4. The bucco elegans, see Plate XXIII. Nat. Hist. fig. 66. or elegant barbet, the most beautiful of the genus.

5. The viridis, or green barbet, is 6½ inches long; the back, the coverts of the wings, and of the tail, are of a very fine green; the head is brown gray; the neck is the same colour, but each feather is edged with yellow.

6. The grandis, or Chinese barbet, is nearly eleven inches long. The principal colour in its plumage is a fine green mixed with blue, which changes with the light. Plate, Nat. Hist. fig. 67.

BUCEROS, in ornithology, the name of a genus in the order of picæ, called in English the hornbill. Birds of this kind have the bill convex, curved, sharp at the edge, of a large size, and serrated outwardly; a horny protuberance on the upper mandible, near the front of the head, nostrils behind the base of the bill, tongue acute and short; feet formed for walking. Of this genus there are thirteen species; the principal of which are,

1. The buceros rhinoceros, distinguished above every other of this extraordinary family by the enormity of its bill. The upper mandible is red toward the base, and of a whitish yellow from thence to the tip; the lower one entirely of a whitish yellow except at the base, where it is black, and hid in the feathers; on the top of the upper mandible is an appendage, as large as the bill itself, and turning upward, contrary to the direction of the bill, both mandibles of which bend downward; this curved horn is variegated with whitish yellow, red, and black, and is as it were divided longitudinally by a line of black on each side. This bird, when full grown, measures four feet from the point of the bill to the tip of the tail. The beak, far from being in proportion to the size of the bird, or useful from its structure, seems to be a cumbrous load to the animal destined to bear it; nature does not furnish another example of a weapon of such magnitude attended with so little effect; the point of it, like that of a lever too far removed from the fulcrum, takes but a feeble hold; it is of a substance so soft, that its edges are continually broken by the least resistance. This singular bird is found in Java, Sumatra, the Philippine islands, and other parts of the East Indies. They are said to feed on flesh and carrion, and that they follow the hunters for the purpose of feeding on the entrails of the beasts which they kill: that they chase rats and mice, and, after pressing them flat, toss them up and catch them in their descent, swallowing them whole.

2. The galeatus, or helmeted hornbill. The prevailing colour of the bird is black; and of the helmet the tops of snuff boxes are sometimes made.

3. The Malabaricus, or pied hornbill. This species is two feet ten inches from the point of the bill to the extremity of the tail. Its bill is eight inches long and two broad, and bent from the straight position; a false bill sits like a horn close on the first, and follows its curvature, and is extended from the case to within two inches of the point. This bird has been called the Indian raven, the horned crow, the horned pie of Ethiopia, &c. When at rest, its head seems to recline on its shoulders; and when disturbed by surprise, it assumes an air of boldness and importance. This bird will eat vegetables and raw flesh; will catch rats, and devour small birds alive. It often repeats a cry like the clacking of a turkey hen when she leads her brood.

4. The bicornis, or Philippine hornbill, according to Brisson is of the size of the turkey hen; but its head is much larger, which indeed is requisite, to support a bill nine inches long, and two inches eight lines thick, and which carries, above the upper mandible, a horny excrescence six inches long, and three inches broad. It inhabits the Philippine islands and the East Indies, and has a cry more like that of a hog or a calf than of a bird; the Gentoos rank it among their gods, and pay adoration to it; it lives chiefly in woods, feeding on wild figs, almonds, and the pistachio nut, which it swallows whole,

and, after the external parts of it have been digested, it brings up the nuts again whole, without the kernels being anywise damaged or unfit for vegetation.

BUCHNERA, in botany, a genus of the angiospermia order, in the didynamia class of plants; ranking, in the natural method, under the 40th order, personatæ. The characters are: the calyx is obscurely 5 toothed: corolla, border, 5 cleft, equal: lobes, cordate: capsule, 2 celled. There are eleven species, natives of the Cape, South America, and the West Indies.

BUCIDA, in botany, a genus of the order monogynia, in the decandria class of plants; ranked, in the natural method, under the 12th order, holeraceæ. The calyx is indented in five segments: it has no corolla; and the fruit is a single seeded berry. There is only one species.

BUCKLER, a piece of defensive armour used by the ancients. It was worn on the left arm, and composed of wickers woven together, or wood of the lightest sort, but most commonly of hides, fortified with plates of brass or other metal.

BUCKRAM, in commerce, a sort of coarse cloth made of hemp, gummed, calendered, and dyed several colours. It is put into those places of the lining of a garment, which are to be stiff and to keep their forms. Sometimes they use new pieces of linen cloth to make buckrams, but most commonly old sheets and pieces of old sails.

BUCKWHEAT. See Polygonum.

BUCKTHORN. See Rhamnus.

BUDDING, a method of propagating various sorts of trees, particularly those of the wall fruit kinds. See Gardening.

BUDDLEIA, in botany, a genus of the monogynia order, in the tetrandria class of plants. The calyx and corolla are quadrifid; the stamina placed at the incisures of the corolla. The capsule is bisulcated, bilocular, and polyspermous. There are eight species, of which three deserve notice.

1. Buddleia Americana, a native of Jamaica and most of the other American islands. It rises to the height of ten or twelve feet, with a thick woody stem covered with gray bark; and sends out many branches toward the top, which come out opposite: at the ends of the branches the flowers are produced in long close spikes branching out in clusters, which are yellow, consisting of one leaf cut into four segments: these are succeeded by oblong capsules filled with small seeds.

2. Buddleia occidentalis, a native of Carthagena. It rises much higher than the other, dividing into a great number of slender branches covered with a russet hairy bark, with long spear shaped leaves ending in sharp points: at the end of the branches are produced branching spikes of white flowers growing in whorls round the stalks, with small spaces between each. All these plants grow in low sheltered spots; their branches being too tender to resist the force of strong winds.

3. Buddleia globosa, a native of Chili, but hardy enough to stand the winter in this climate. It is a beautiful shrub. The flowers are of an orange colour, in close pedunculed heads, two together on opposite sides of the branches.

BUDGE BARRELS, among engineers, small barrels well hooped, with only one head; on the other end is nailed a piece of leather, to draw together upon strings like a purse. Their use is for carrying powder along with a gun or mortar, being less dangerous, and easier carried, than whole barrels. They are likewise used upon a battery of mortars, for holding meal powder.

BUFF, in commerce, a sort of leather prepared from the skin of the buffalo, dressed with oil, after the manner of shammy. This makes a very considerable article in the French, English, and Dutch commerce at Constantinople, Smyrna, and all along the coast of Africa. The skins of elks, oxen, and other like animals, when prepared after the same manner as that of the buffalo, are likewise called buffs.

Of buff skin, or buff leather, are made a sort of coats for the horse or gens-d'armes of France, bandaliers, belts, ponches, and gloves.

BUFFALO. See Bos.

BUFONIA, toad grass: a genus of the digynia order, belonging to the tetrandria class of plants; and in the natural method ranking under the 22d order, caryophylleæ. The calyx is 4 leaved: the corolla, 4 petaled: the capsula is monospermous. There is but one species, a native of Britain.

BUG. See Cimex.

BUGGASINS, in commerce, a name given to buckrams made of calico.

BUGLOSS. See Anchusa.

BUILDING. See Architecture.

Buildings, *laws concerning*. The buildings of London are regulated by what is denominated the building act, which repeals and amends several former acts for the same purpose. It was passed in the year 1774, and begins by dividing all buildings into seven rates or classes, for the purpose of subjecting them to various regulations respecting the thickness of the walls, &c. Surveyors of districts are appointed to see the rules and regulations of this act properly complied with. Before any building is begun to be erected, the master workman is bound to give twenty-four hours notice to the surveyor, who is to attend and view the building, and enforce the observance of the act. The fees to be paid by the builder to the surveyor are, for a building of the first rate, 3*l.* 10*s.* and for an alteration or addition, 1*l.* 15*s.* for a building of the second rate, 3*l.* 3*s.* and for an alteration 1*l.* 10*s.* for the third rate, 2*l.* 10*s.* and 1*l.* 5*s.* and for the fourth rate, 1*l.* 1*s.* and 15*s.*

BULBOCODIUM, mountain saffron: a genus of the monogynia order, in the hexandria class of plants; and in the natural method ranking under the ninth order, spathaceæ. The corolla is funnel shaped, and hexapetalous, with the heels narrow, supporting the stamina. There is one species,

Bulbocodium vernum, which is a native of Spain, and has a bulbous root shaped like those of the snow drop, which sends out three or four spear shaped concave leaves, between which comes out the flower, standing on a very short footstalk. The flowers appear about the same time with the last; at first they are of a pale colour, but afterward change to a whitish purple.

BULIMY, a disease in which the patient is affected with an insatiable and perpetual desire of eating; and, unless he is indulged, he often falls into fainting fits. It is also called *fames canina*, canine appetite. See Medicine.

BULK HEADS are partitions made athwart the ship, with boards, by which one part is divided from the other; as the great cabin, gun room, bread room, and several other divisions. The bulk head before is the partition between the forecastle and grating in the head.

BULL. See Bos.

BULL'S EYE, among seamen, a small, obscure, sublime cloud, ruddy in the middle, that sometimes appears to mariners, and is the immediate forerunner of a great storm at sea. It is also used for a small oval block of hard wood, without sheaves. It is turned in a lathe, has a groove round the outside, and an oval hole gouged through the middle.

Bull, among ecclesiastics, a written letter, despatched, by order of the pope, from the Roman chancery, and sealed with lead, being written on parchment, by which it is partly distinguished from a brief. It is a kind of apostolical rescript, or edict, and is chiefly in use in matters of justice or grace. If the former is the intention of the bull, the lead is hung by a hempen cord; if the latter, by a silken thread. It is this pendent lead, or seal, which is, properly speaking, the bull; and which is impressed, on one side, with the heads of St. Peter and St. Paul, and on the other with the name of the pope, and the year of his pontificate. The bull is written in an old, round, Gothic letter, and is divided into five parts; the narrative of the fact, the conception, the clause, the date, and the salutation, in which the pope styles himself servus servorum, *i.e.* the servant of servants. These instruments, besides the lead hanging to them, have a cross, with some text of Scripture, or religious motto, about it. Bulls are granted for the consecration of bishops, the promotion to benefices, and the celebration of jubilees, &c.

Bull, *in cœna Domini*, a particular bull read every year, on the day of the Lord's supper, or Maundy Thursday, in the pope's presence, containing excommunications and anathemas against heretics, and all who disturb or oppose the jurisdiction of the holy see. After the reading of the bull, the pope throws a burning torch into the public place, to denote the thunder of this anathema.

Bull, golden, an edict, or imperial constitution, made by the emperor Charles IV. reputed to be the magna charta, or the fundamental law, of the German empire. It is called golden, because it has a golden seal, in the form of a pope's bull, tied with yellow and red cords of silk; upon one side is the emperor represented sitting on his throne, and on the other the capitol of Rome. It is also called Caroline, on Charles IV's account. Till the publication of the golden bull, the form and ceremony of the election of an emperor were dubious and undetermined, and the number of the electors not fixed. This solemn edict regulated the functions, rights, privileges, and pre-eminences of the electors. The original, which is in Latin, on vellum, is preserved at Frankfort: this ordonnance, containing thirty articles, or chapters, was approved of by all the princes of the empire, and remains still in force.

BULLA, in conchology, the name of a genus of shells, the character of which is thus defined: animal a limax; shell univalve, convoluted, and unarmed; mouth or aperture somewhat straightened, oblong, longitudinal, and at the base very entire; pillar lip oblique and smooth. There are many species.

BULLÆ, in Roman antiquity, ornaments at first given only to the sons of noblemen; though afterward they became of more common use. This ornament was first given by Tarquinius with the prætexta to his son, who had, with his own hand, at fourteen years of age, killed an enemy.

BULLION, uncoined gold or silver in the mass.

Those metals are called so, either when smelted from the native oar, and not perfectly refined, or when they are perfectly refined but melted down in bars or ingots, or in any unwrought body of any degree of fineness.

When gold and silver are in their purity, they are so soft and flexible that they cannot well be brought into any fashion for use, without being first reduced and hardened with an alloy of some other baser metal. To prevent abuses, according to the laws of England, all sorts of wrought plate in general ought to be made to the legal standard: and the price of our standard gold and silver, the common rule whereby to set a value on their bullion, whether the same is in ingots, bars, dust, or in foreign specie; whence it is easy to conceive that the value of bullion cannot be exactly known without being first assayed, that the exact quantity of pure metal therein contained may be determined, and consequently whether it is above or below the standard.

BUMALDA, in botany, a genus of the digynia order, belonging to the pentandria class of plants. The corolla is five petaled, styles villose, capsule two celled, two beaked. There is one species, a native of Japan.

BUMELIA, a genus of the class and order pentandria monogynia. The essential character is, corolla five cleft, with five leaved nectary, drupe one seeded. There are seven species, all trees and shrubs, natives of the West Indies, called there bastard bully tree.

BUMICILLI, a religious sect of Mahometans in Egypt and Barbary, who pretend to fight with devils, and commonly appear in a fright and covered with wounds and bruises.

BUNIAS, in botany, a genus of the order siliquosa, and tetradynamia class of plants, and ranking under the thirty-ninth natural order, siliquosæ. The siliqua is deciduous, four sided, muricated, or shagreened with unequal pointed angles. There are nine species, all annual plants, but none of them possessed of any remarkable property.

BUNIUM, pig nut, or earth nut, in botany, a genus of the digynia order and pentandria class of plants, and in the natural method ranking under the 45th order, umbellatæ. The corolla is uniform, the umbel thick, and the fruit ovate. There is but one known species, *viz.*

Bunium bulbocastanum, with a globular root. It grows naturally in moist pastures in Britain, and has a tuberous solid root, which lies deep in the ground. The leaves are finely cut, and lie near the ground. The stalk rises a foot and a half high, is round, channelled, and solid. The flowers are white, and shaped like those of other umbelliferous plants; the seeds are small, oblong, and when ripe are channelled. The roots of this sort are frequently dug up, and by some people eaten raw. They have much resemblance in taste to a chesnut, whence the specific name.

BUNT *of a sail*, the middle part of it, formed designedly into a bag or cavity, that the sail may gather more

wind. It is used mostly in topsails, because courses are generally cut square, or with but small allowance for bunt or compass. The bunt holds much leeward wind, that is, it hangs much to leeward.

Seamen all agree that a bellying or bunting sail carries a vessel faster to the windward than a straight or fast sail.

Bunt lines are small lines made fast to the bottom of the sails, in the middle part of the bolt rope, to a cringle, and so are reeved through a small block, seized to the yard. Their use is to trice up the bunt of the sail, for the better furling it up.

BUOY, at sea, a short piece of wood, or a close hooped barrel, fastened so as to float directly over the anchor, that the men who go in the boat to weigh the anchor, may know where it lies.

Buoy is also a piece of wood or cork, sometimes an empty cask, well closed, swimming on the surface of the water, and fastened by a chain or cord to a large stone, piece of broken cannon, or the like, serving to mark the dangerous places near a coast, as rocks, shoals, wrecks of vessels, anchors, &c.

Stream the buoy, is to let the anchor fall while the ship has way.

To buoy up the cable is to fasten some pieces of wood, barrels, &c. to the cable near the anchor, that the cable may not touch the ground in case it be foul or rocky, lest it should be fretted and cut off.

BUPHAGA, in ornithology, a genus of the order of picæ, of which only a single species, Africana, see Plate XXIII. Nat. Hist. fig. 68. has been discovered. Its character is, the bill straight and somewhat quadrangular; mandibles gibbous, entire, and more gibbous on the outside; legs formed for walking. It is found in Africa, and is called in English the beef eater from this peculiarity; that it sometimes alights upon the backs of cattle, and picks holes in them in order to get at the larvæ of the œstri, or gadflies, deposited by those creatures in the flesh directly below the skin.

BUPHTHALMUM, *ox eye*, a genus of the polygamia superflua order, and syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The receptacle is paleaceous; the pappus an indifferent rim; the seeds, especially those of the radius, emarginated on the sides; the stigmata of the hermaphrodite florets undivided. There are twelve species, all of which may be propagated by seeds; and those which do not, by parting their roots, or cutting off their branches. Some of the species are tender, and require to be raised on a hot bed. The following are the most remarkable:

1. Buphthalmum arborescens, rises with several woody stems to the height of eight or ten feet. The flowers are produced at the ends of the branches; they are of a pale yellow colour, and have scaly empalements.

2. Buphthalmum helianthoides, a native of North America. It has a perennial root, and an annual stalk which rises six or eight feet high. The flowers come out at the extremities of the branches, and are of a bright yellow colour, resembling a small sunflower.

BUPLEURUM, *hare's ear*, or thorough wax, a genus of the digynia order, and pentandria class of plants, and in the natural method ranking under the 45th order, umbellatæ. The involucra of the partial umbels are large in proportion, and pentaphyllous; the petals involuted or rolled inward; the fruit roundish, compressed and striated. There are 14 species, the principal of which is,

Bupleurum fruticosum, or shrubby Ethiopian hartwort. It rises with a shrubby stem, dividing into numerous branches, forming a bushy head five or six feet high, adorned with oblong, oval, entire leaves of a sea green colour, placed alternate, with yellow flowers in umbels at the ends of the branches, which appear in July and August, and are sometimes succeeded by ripe seeds. It may be propagated by cuttings.

BUPRESTIS, a genus of coleopterous insects, distinguished in a peculiar manner by the uncommon brilliancy and highly metallic splendour of their colours, which emulate the finest and most beautifully polished metals. The insects of this genus, which are very numerous, have the antennæ serrated, and as long as the thorax; feelers four, which are all filiform, with the last joint obtuse or truncated; head partly retracted within the thorax. The larvæ of the buprestes are said to live in the solid wood, or in the trunks of decayed trees; but this is doubted by some naturalists, since they do not appear to be exactly known in that state. The conjecture is, however, plausible, as the perfect insects are almost constantly found upon trees, or plants and flowers. Few species of this beautiful tribe of insects are found in Europe: the largest and most brilliant of those discovered are from the Brazils, and other hot countries, among which is the buprestis vittata. See Plate XXIII. Nat. Hist. fig. 69. There are in all 27 species.

BURBAS, in commerce, a small coin at Algiers with the arms of the dey struck on both sides. It is worth half an asper.

BURBER, an Egyptian piece of copper money, twelve of which make a medine.

BURCARDIA, a genus of the class and order pentandria pentagynia. The essential character is, calyx five leaved; corolla five petaled; capsule angular, one celled, three valved, seven or eight seeded. There is one species, a native of Guiana, annual.

BURDEN *of a ship*, is its contents or number of tons it will carry. The burden of a ship may be determined thus: multiply the length of the keel, taken within board, by the breadth of the ship, within board, taken from the midship beam; from plank to plank and multiply the product by the depth of the hold, taken from the plank below the keelson, to the under part of the upper deck plank, and divide the last product by 94, then the quotient is the content of the tonnage required.

BURGAGE, an ancient tenure in boroughs, whereby the inhabitants, by custom, hold their lands, &c. of the king, or other superior lord of the borough, at a certain yearly rent; also a dwelling house in a borough was anciently called a burgage.

BURGLARY, the breaking and entering the mansion house of another in the night, with intent to commit some felony within the same, whether the felonious intent be executed or not. Hale's Pl. 79. But there must be a breaking and entry to complete this offence. 1 Haw. c. 38. s. 3. If there be daylight enough, begun or left, to discern a man's face, it is no burglary. This however does not extend to moonlight, for then many burglaries would go unpunished. 4 Blacks. 224.

Every entrance into a house by trespass is not a breaking in this case; for there must be an actual breaking. If the door of a mansion should stand open, and the thief enter, this is not a breaking; or if the window of an house be open, and a thief with a hook or other instrument should draw out some of the goods of the owner, this is no burglary, because there is no actual breaking. But if the thief should break the glass of the window, and with a hook or other instrument draw out some of the goods of the owner, this is a burglary, for there is an actual breaking of the house. 3 Inst. 64.

The mansion house does not only include the dwelling house, but also the outhouses that are parcel thereof, though not under the same roof, or joining contiguous to it; but if they be far remote from the dwelling house, and not so near it as to be reasonably esteemed parcel thereof, then the breaking is not burglary. H. H. 553. To break and enter a shop, not parcel of the mansion house, in which the shopkeeper never lodges, but only works or trades there in the day time, is not a burglary, but only larceny; but if he or his servant, usually or often lodge in the shop at night, it is then a mansion house, in which a burglary may be committed. Ib. Where the owner leaves his house and disfurnishes it, without a settled resolution of returning, it cannot under these circumstances be deemed a dwelling house; but where the owner quits the house in order to return occasionally, though no person be left in it, it may still be considered as his mansion house. Fost. 76. A chamber in an inn of court, &c. where one usually lodges, is a mansion house, for every one has a several property there, but a chamber where any person lodges as an inmate cannot be called his mansion, though if a burglary be committed in his lodgings, the indictment may lay the offence to be in the mansion house of him that let them. 3 Inst. 65. If the owner live under the same roof with the inmates, there must be a separate outer door, or the whole is the mansion of the owner; but if the owner inhabit no part of the house, or even if he occupies a shop or cellar in it, but do not sleep therein, it is the mansion of each lodger, though there be but one outer door. Leach's Haw. c. 38. s. 15.

By the 18 Eliz. c. 7. s. 1. it is enacted, that if any person shall commit any felonious rape, ravishment, or burglary, and be found guilty by verdict, or shall be outlawed, or shall confess such rape or burglary, every person so found guilty shall suffer death, and forfeit as in cases of felony without benefit of clergy. But in all cases of burglary, accessaries after must have their clergy. 1 Haw. 557.

The court may allow a prosecutor who has bona fide prosecuted, such sum as they shall think reasonable, not exceeding the expenses he was bona fide put to; making also, if he shall appear to be in poor circumstances, a reasonable allowance for his trouble and loss of time. 18 Geo. III. c. 19.

And further, any person who shall apprehend any one guilty of burglary, and prosecute him to conviction, shall have a certificate without fee, to be made out and delivered before the end of the assizes, under the hand of the judge, certifying the conviction, and in what parish the burglary was committed, and that the burglar was taken by the person or persons claiming the reward; and if any dispute should arise between the parties claiming, the judge shall by such certificate, direct the same to be paid and distributed among them as to him shall seem just and reasonable; and on tendering such certificate to the sheriff, and demand made, he shall pay to the person or persons so entitled the sum of 40*l.* without any deduction. 5 Anne, c. 31. 6 Geo. 23. s. 10. Such certificate shall be enrolled by the clerk of the peace of the county in which it shall be granted, for which he shall have 1*s.* And the said certificate may be once assigned over, and the original proprietor or assignee of the same shall, by virtue thereof, be discharged from all manner of parish and ward offices, within the parish and ward where the felony was committed. 10 and 11 Wm. c. 23.

BURGOMASTER, the chief magistrate of the great towns in Flanders, Holland, and Germany. The power and jurisdiction of the burgomaster are not the same in all places, every town having its particular customs and regulations. At Amsterdam there are four, chosen by the voices of all those people in the senate, who have either been burgomasters or echevins. Their authority resembles that of our lord mayor and aldermen; they dispose of all under offices that fall in their time, keep the key of the bank, and enjoy a salary but of five hundred guilders; all feasts, public entertainments, &c. being defrayed out of the common treasury.

BURIAL. Among the Jews, the privilege of burial was denied only to self murderers, who were thrown out to rot upon the ground. In the Christian church, though good men always desired the privilege of interment, yet they were not, like the heathens, so concerned for their bodies as to think it any detriment to them, if either the barbarity of an enemy, or some other accident, deprived them of this privilege. The primitive Christian church denied the more solemn rites of burial only to unbaptized persons, self murderers, and excommunicated persons who continued obstinate and impenitent, in manifest contempt of the church's censures.

The place of burial among the Jews was never particularly determined. We find they had graves in the town and country, upon the highways, in gardens, and upon mountains. Among the Greeks, the temples were made repositories for the dead in the primitive ages; yet the general custom in later ages with them, as well as with the Romans and other heathen nations, was to bury their dead without their cities, and chiefly by the highways. Among the primitive Christians, burying in cities was not allowed for the first three hundred years, nor in churches for many ages after; the dead bodies being first deposited in the atrium or church yard, and porches and porticoes of the church: hereditary burying places were forbidden till the twelfth century.

By the laws of England, persons dying are to be buried in woollen, or their representatives shall forfeit 5*l.* and affidavit is to be made thereof before a justice under a like penalty. The minister is to keep a register at the parish expense.

BURMANNIA, a genus of the monogynia order, in the hexandria class of plants; ranked in the natural method under the 10th order, coronariæ. The flower is small, and consists of three minute, ovated, oblong petals, situated at the mouth of the cup; the fruit is an involuted

capsule, formed of three valves, with three cells, containing many small seeds. There are two species, of no note.

BURN. See Surgery.

BURNING GLASS, a convex or concave glass, commonly spherical, which being exposed directly to the sun, collects all the rays falling on it into a very small space, called the focus, where wood, or any other combustible matter being put, will be set on fire. The convex burning glasses transmit the rays of light, and in their passage refract or incline them toward the axis, having the property of lenses, and acting according to the laws of refraction. The concave burning glasses, or rather mirrors, being usually made of metal, reflect the rays of light, and in that reflection incline them to a point in the axis, having the property of mirrors, and acting according to the laws of reflection. See Optics.

BURNISHER, a round polished piece of steel, serving to smooth and give a lustre to metals. Of these there are different kinds, of different figures, straight, crooked, &c. Half burnishers are used to solder silver, as well as to give a lustre.

Book binders burnish the edges of their books by rubbing them with a dog's tooth. Gold and silver are burnished by rubbing them with a wolf's tooth, or by the bloody stone, or by tripoll, a piece of white wood, emery, &c. Deer are said to burnish their heads by rubbing off a downy white skin from their horns against a tree.

BURR PUMP, or Bilge pump, differs from the common pump in having a staff 6, 7, or 8 feet long, with a bar of wood to which the leather is nailed, and this serves instead of a box. Two men, standing over the pump, thrust down this staff, to the middle whereof is fastened a rope, for 6, 8, or 10 to hale by, thus pulling it up and down.

BURTON, in the sea language, a small tackle consisting of two single blocks: it may be made fast any where at pleasure, for hoisting small things in and out, and will purchase more than a single tackle with two blocks.

BURSERA, in botany, a genus of the dioecia polygamia class and order. The hermaphrodite calyx is triphyllous; the corolla tripetalous: the male capsule carnous, trivalved, and monospermous. The male is, corolla five petaled, stamina ten. There is but one species, *viz.*

Bursera gummifera, or gum elemi, see Plate XXIII. Nat. Hist. fig 70. It is frequent in woods in most of the Bahama islands, and grows speedily to a great height and thickness. The bark is brown and very like the birch. The wood is soft and useless, except when pieces of the limbs are put into the ground as fences, when it grows readily, and becomes a durable barrier. The leaves are pinnate: the middle rib 3 or 6 inches long, with the pinnæ set opposite on footstalks half an inch long. It has yellow flowers, male and female on different trees. These are succeeded by purple coloured berries bigger than large peas, hanging in clusters on a stalk of about 5 inches long, to which each berry is joined by a footstalk half an inch long. The seed is hard, white, and of a triangular figure, enclosed within a thin capsule, which divides in 3 parts and discharges the seed. The fruit when cut discharges a clear balsam, esteemed a good vulnerary, particularly for horses. On wounding the bark, a thick milky liquor is obtained, which soon concretes into a resin no way different from the gum elemi of the shops.

BUSHEL, a measure of capacity for dry goods, as grain, fruits, dry pulse, &c. containing four pecks or eight gallons, or one eighth of a quarter. A bushel, by 12 Henry VIII. c. 5. is to contain eight gallons of wheat; the gallon eight pounds of troy weight; the ounce twenty sterlings, and the sterling thirty-two grains, or corns of wheat, growing in the midst of the ear.

This standard bushel is kept in the exchequer, and it is found to contain 2145.6 solid inches, and the water with which it has been filled weighed 1131 ounces and fourteen pennyweights troy. By act of parliament made in 1697, it is determined that every round bushel with a plain and even bottom, being 18½ inches in diameter, and 8 inches deep, should be esteemed a legal Winchester bushel according to the standard in his majesty's exchequer. A vessel thus made will contain 2150.42 cubic inches, of course the corn gallon contains 268.8 cubic inches. Besides the standard or legal bushel, there are several local bushels of different dimensions in different places.

Buskin, a kind of shoe, somewhat in the manner of a boot, and adapted to either foot, and worn by either sex. This part of dress, covering both the foot and mid leg, was tied underneath the knee; it was very rich and fine, and principally used on the stage by actors in tragedy. It was of a quadrangular form, and the sole was so thick, as that by means of it, men of the ordinary stature might be raised to the pitch and elevation of the heroes they personated. The colour was generally purple on the stage: herein it was distinguished from the sock, worn in comedy, that being only a low common shoe. The buskin seems to have been worn not only by actors, but by girls, to raise their height: travellers and hunters also made use of it to defend themselves from the mire.

BUSS, in maritime affairs, a small sea vessel, used by us and the Dutch in the herring fishery, commonly from 48 to 60 tons burden, and sometimes more. A buss has two small sheds or cabins, one at the prow, and the other at the stern; that at the prow serves for a kitchen.

BUTCHER *bird*, in ornithology. See Lanius.

BUTEA, in botany, in honour of the late marquis of Bute. Class and order diadelphia decandria; nat. ord. papilionaceæ; calyx sublabiate; corolla standard very long, lanceolate; legume compressed, membranaceous, with one seed at the summit. There are two species; one an evergreen tree, about 15 feet high, from which, when cut, exudes a gummy blood red juice, of a sweetish taste. The second differs but little from the preceding. They are both natives of the East Indies, on the coasts of Malabar and Coromandel.

BUTNERIA, a genus of the pentandria monogynia class and order. The essential character is; cor. five petaled, filaments at top, connate with the petals; caps. five grained, muricate. There are three species, shrubs of America and the West Indies.

BUTOMUS, the *flowering rush*, or *water gladiole;* a genus of the hexagynia order, in the enneandria class of plants, ranking, in the natural method, under the 5th order, tripetaloideæ. There is no calyx, but it has six petals, and as many monospermous capsules. There is but one species, *viz.*

Butomus umbellatus, of which there are two varieties, the one with a white, the other with a rose coloured, flower. Though common plants, they are very pretty, and

are worth propagating in a garden where there is conveniency for an artificial bog, or where there are ponds of standing water, as is many times the case. Where these conveniencies are wanting, they may be planted in cisterns, which should be kept filled with water, with about a foot thickness of earth in the bottom; and into this earth the roots should be planted, or the seeds sown as soon as they are ripe.

BUTT, in commerce, a vessel or measure of wine containing two hogsheads, or 126 gallons.

Butt, or *butt ends*, in the sea language, are the fore ends of all planks under water, as they rise, and are joined one end to another. Butt ends in great ships are most carefully bolted; for if any one of them should spring or give way, the leak would be very dangerous and difficult to stop.

BUTTER, a fat unctuous substance, prepared from milk by the process of churning. It was late before the Greeks appear to have had any notion of butter; their poets make no mention of it, and yet frequently speak of milk and cheese. The Romans used butter no otherwise than as a medicine, never as a food. The ancient Christians of Egypt burnt butter in their lamps instead of oil; and in the Roman churches, it was anciently allowed, during Christmas time, to burn butter instead of oil, on account of the great consumption of it otherwise.

BUTTOCK *of a ship*, is that part of her which is her breadth right astern, from the tack upward; and a ship is said to have a broad or a narrow buttock, according as she is built broad or narrow at the transum.

BUTTON, an article of dress, serving to fasten clothes tight about the body, made of metal, silk, mohair, &c. in various forms. Metal buttons are formed two different ways; the blanks, or bases of the button, are either pierced out of a large sheet of metal, or cast. In the latter case, the shanks are previously fixed in the sand, exactly in the centre of the impression formed by each pattern, so as to have their extremities immersed in the melted metal, by which means they are firmly fixed in the button when cooled. The former process is generally used for yellow buttons, and the latter for those of white metal.

The metal used for gilt buttons is an alloy of copper and zinc, containing more copper than goes to the composition of brass. This metal is rolled into sheets, and the blanks pierced out; these are then planished, if for plain buttons; but when ornamented buttons are wanted the die is now struck, unless great nicety is required, when they are wrought by the hand. The shanks, made with great expedition by a curious engine, are then attached to the bottom of each button by a wire clamp, like a pair of sugartongs, and a small quantity of solder and resin applied to each. They are then exposed to heat on an iron plate, containing about a gross, till the solder runs, and the shank becomes fixed to the button, after which they are singly put into a lathe, and their edges turned off smoothly. The surface of the metal, which has become in a small degree oxidated by the action of the heat, is to be cleaned by means of diluted nitric acid. The next step in the business is the rough burnishing, which is done in a lathe with a hard black stone, from Derbyshire. After this comes the gilding; which is done by first covering the surface uniformly with a thin stratum of mercury, and upon this is to be laid an amalgam, made of mercury and gold; five grains of gold will cover 144 buttons, each one inch in diameter. The mercury is now to be volatilized by means of heat.

Glass buttons are composed of glass of various colours, in imitation of opal, lapis lazuli, and other stones. The glass is kept in fusion, and the button nipped out of it whilst in its plastic state, by a pair of iron moulds, like those for casting pistol shot, adapted to the intended form of the button; the shank having been inserted in the mould so that it may become imbedded in the glass when cool.

Shell buttons are those which consist of a back, generally made of bone, without any shank, but corded with catgut, and covered in front with a thin plate of metal struck with a die. The backs are cut out with a brace, the bit of which is a circular saw, and the four holes through which the catgut passes are drilled by four drills moving parallel to each other, and acting at once. They are then corded by children, who tie the catgut on the inside; the cavity is filled with melted resin, and the metal shell applied warm. The button is then pressed between two centres in a lathe, which are forced together by a weight acting on a lever, and the edge of the shell turned down during its revolution with a small burnisher.

Button *stone*, in natural history, a figured stone, so named from its resembling the button of a garment. There are three sorts, which Dr. Hook supposes to have been nothing but the filling up of three several sorts of shells. They are very hard flints, and consist of two bodies. This name is also given to a peculiar species of slate, found in some parts of Germany, that runs with ease into glass, in the course of a few hours, without the addition of any salt, or other foreign substance, to promote its vitrification. It, in fact, contains in itself all the principles of glass, and from it the Swedes and Germans make glass buttons, the handles of knives, and other articles.

BUTTS, or Backs, a name given to that sort of tanned leather which is prepared from the stoutest and heaviest ox hides, and is chiefly used for the soles of shoes.

BUXBAUMIA, in botany, a genus of the order musci, belonging to the cryptogamia class of plants: ranking under the same order, musci, or mosses, in the natural method.

BUXUS, the *box tree;* a genus of the tetrandria order, and monoecia class of plants; and in the natural method ranking under the 38th order, tricoccæ. The male calyx is triphyllous; the germen an embryo, or imperfect rudiment. The female calyx is tetraphyllous: there are three petals, and as many styles: the capsule is three beaked and trilocular, with two seeds. There is one species, with three varieties.

1. Buxus angustifolia, the narrow leaved box. 2. Buxus arborescens, with oval leaves. These two varieties grow in great plenty upon Boxhill, near Dorking, in Surry. Here were formerly many large trees of that kind, but now they are few in number. There are two or three varieties of the second sort, which are propagated in gardens; one with yellow, and the other with white striped leaves. Another has the tips of the leaves only marked with yellow, and is called tipped box. Both these may be raised from seeds, or propagated by cuttings, planted in autumn in a shady border. The best season for removing these trees is in October; though if care is used to take them up with a ball of earth, they may be transplanted almost at any

time, except the middle of summer. Box wood is extremely hard and smooth, and therefore well adapted to the use of the turner. Combs, mathematical instruments, knife handles, and button moulds, are made of it. It may properly enough be substituted in default of ebony, the yellow alburnum of which it perfectly resembles. Neither the wood nor the leaves of the box tree at present are used for any other medicinal purpose than the distillation of an empyreumatic oil; and an oil of nearly the same quality is obtained from almost every other wood.

3. Buxus suffruticosa, dwarf or Dutch box, commonly used for bordering flower beds. It is increased by parting the roots, or planting the slips; but as it makes a great increase of itself, and easily parts, it is hardly worth while to plant the slips that have no roots. For borders to flower plots, it far excels any other plant. It is of long duration; is easily kept handsome; and by the firmness of its rooting, keeps the mould in the borders from washing into the gravel walks more effectually than any plant whatever.

BUZZARD. See FALCO.

BUYING and SELLING, a transferring of property from one person to another, in consideration of some price or recompense. On an agreement for goods, the vendee cannot carry them away without payment, unless the vendor agrees to trust him. But if any part of the price is laid down, or any portion of the goods delivered by way of earnest, the vendee may recover the goods by action, as well as the vendor may the price of them. By 29 C. II. c. 3. no contract for the sale of goods, to the value of 10*l.* or upward shall be valid, unless the payment or delivery be performed, or unless some note in writing be made and signed by the party or his agent. But if a vendee, after a bargain is struck, tenders the money, and the vendor refuses it, the property is absolutely vested in the vendee.

BYLAW, is a private law made by those who are duly authorized so to do by charter, prescription, or custom, for the preservation of order and good government, within some particular place or jurisdiction. Moor, 583.

Every corporation, lawfully erected, has power to make bylaws, or private statutes, for the better government of the corporation; which are binding upon themselves, unless contrary to the laws of the land, and then they are void. 11 Blacks. 475.

BYSSUS, in botany, a genus of mosses, belonging to the order algæ, in the cryptogamia class of plants: the characters are; that the mosses of it are composed of simple and uniform parts, and always appear in form of excrescences, either of a woolly or of a dusty matter. It seems properly a genus of a middle kind, between the mushrooms and the mosses, but most approaching to the latter; as the several species of it are of longer duration, and want that fleshy texture which distinguishes the fungus class; and as they never produce heads, nor have any thing of the figure or texture of fungi. There are 19 species, natives of Britain, which grow upon old walls, rotten wood, &c. They are also found in many parts of Europe, covering the ground like a carpet.

BYSSUS asbestinus, a species of asbestus or incombustible flax, composed of flexible parallel fibres. It is found plentifully in Sweden, either white, or of different shades of green. At a copper mine in Westmannland, it forms the greatest part of the vein out of which the ore is dug: and by the heat of the furnace which melts the metal, is changed into a pure semitransparent glass.

BYSSUS, in antiquity, that fine Egyptian linen of which the tunics of the Jewish priests were made.

BYSTROPOGON, a genus of the didynamia gymnospermia class and order. The essential character is: cal. five subulated, bearded at the opening; cor. upper lip bifid, lower trifid; stam. distant. There are seven species, but none deserving particular notice.

C.

C, the third letter of the alphabet. C, in music, is the highest part in the thorough base; again, a simple C, or rather a semicircle, placed after the clef, intimates that the music is in common time, which is either quick or slow, as it is joined with allegro or adagio; if alone, it is usually adagio. If the C is crossed or turned, the first requires the air to be played quick, and the last very quick.

CAABA, or CAABAH, properly signifies a square building, but is particularly applied by the Mohammedans to the temple of Mecca, built, as they pretend, by Abraham, and Ishmael his son. It is toward this temple they always turn their faces when they pray, in whatever part of the world they happen to be. This temple enjoys the privilege of an asylum for all sorts of criminals; but it is most remarkable for the pilgrimages made to it by the devout mussulmen, who pay so great a veneration to it, that they believe a single sight of its sacred walls, without any particular act of devotion, is as meritorious in the sight of God, as the most careful discharge of their duty, for the space of a whole year, in any other temple.

CAB, an Hebrew dry measure, containing two five-sixths pints of our corn measure.

CABALLEROS, or CAVALLEROS, are Spanish wools, of which there is a considerable trade at Bayonne, in France.

CABBAGE. See BRASSICA.

Any person who shall steal, or take away, or maliciously pull up and destroy, any turnips, potatoes, cabbages, parsneps, peas, or carrots, growing in any lands, &c. shall, on conviction before one justice, by confession, or oath of one witness, forfeit, over and above the value of the goods stolen, a sum not exceeding 20*s.* one half to the owner of the goods, and one half to the poor.

CABBALA, according to the Hebrew style, has a very different signification from that wherein we understand it in our language. The Hebrew cabbala signifies tradition; and the rabbis, who are called cabbalists, study

principally the combination of particular words, letters, and numbers, and by this means pretend to discover what is to come, and to see clearly into the sense of many difficult passages in Scripture: there are no sure principles of this knowledge, but it depends upon some particular traditions of the ancients; for which reason it is termed cabbala.

The cabbalists have abundance of names, which they call sacred; these they make use of in invoking of spirits, and imagine that they receive great light from them. They tell us that the secrets of the cabbala were discovered to Moses on mount Sinai, and that these have been delivered down to them from father to son, without interruption, and without any use of letters; for to write them down is what they are by no means permitted to do. This is likewise termed the oral law, because it passed from father to son, in order to distinguish it from the written laws.

There is another cabbala, called artificial, which consists in searching for abstruse and mysterious significations of a word in Scripture, whence they borrow certain explanations, by combining the letters which compose it. This cabbala is divided into three kinds, the gematrie, the notaricon, and the temura or themurah: the first of which consists in taking the letters of a Hebrew word for cyphers or arithmetical numbers, and explaining every word by the arithmetical value of the letters whereof it is composed. The second sort of cabbala, called notaricon, consists in taking every particular letter of a word for an entire diction; and the third, called themurah, *i.e.* change, consists in making different transpositions or changes of letters, placing one for the other, or one before the other.

Among the Christians likewise, a certain sort of magic is by mistake called cabbala, which consists in using improperly certain passages of Scripture for magic operations, or in forming magic characters or figures with stars and talismans.

Some visionaries among the Jews believe that Jesus Christ wrought his miracles by virtue of the mysteries of the cabbala.

CABECA, or Cabesse, a name given to the finest silks in the East Indies, as those from 15 to 20 per. cent. inferior to them are called barina.

CABIDOS, or Cavidos, a long measure used at Goa, and in other places of the East Indies belonging to the Portuguese, to measure stuffs, linens, &c. and equal to four sevenths of the Paris ell.

CABLE, a thick, large, strong rope, commonly of hemp, which serves to keep a ship at anchor. There is no merchant ship, however small, but has at least three cables; *viz.* the chief cable, or cable of the sheet anchor, a common cable, and a smaller one. Cable is also said of ropes which serve to raise heavy loads, by the help of cranes, pulleys, and other engines. The name of cable is usually given to such as have at least three inches in diameter; those that are less are only called ropes, of different names according to their use. Every cable, of what thickness soever it may be, is composed of three strands, every strand of three ropes, and every rope of three twists; the twist is made of more or less threads, according as the cable is to be thicker or thinner. In the manufacture of cables, after the ropes are made, they use sticks, which they pass first between the ropes of which they make the strands, and afterward between the strands of which they make the cable, to the end that they may all twist the better, and be more regularly wound together; and also, to prevent them from twining or entangling, they hang at the end of each strand and of each rope, a weight of lead or of stone. The number of threads each cable is composed of is always proportioned to its length and thickness; and it is by this number of threads that its weight and value are ascertained. Thus a cable of three inches circumference, or one inch diameter, ought to consist of 48 ordinary threads, and weigh 192 pounds: and on this foundation is calculated the following table.

Circumf.	Threads.	Weight.
3 inches.	48	192 pounds.
4	77	308
5	121	484
6	174	696
7	238	952
8	311	1244
9	393	1572
10	485	1940
11	598	2392
12	699	2796
13	821	3284
14	952	3808
15	1093	4372
16	1244	4976
17	1404	5616
18	1574	6296
19	1754	7016
20	1943	7772.

A patent has been taken out within these few months by Mr. Haddart, for improvements in the manufacture of cables.

Pay more Cable, is to let more out of the ship. Pay cheap the cable, is to hand it out apace. Veer more cable, is to let more out, &c.

Cable's *length*, is 120 fathoms. This regulates the distance of ships of war when formed into a line of battle, which is ordered to be one or more cables length.

Slip the Cable, is to let it run quite out when there is not time to weigh the anchor: this is preferable to cuting it. Before it is either cut or slipped, a spare buoy rope should be passed through the hawse hole, and fastened near the end, with a rolling nitch, that it and the anchor may be easily regained.

CABLED, in heraldry, a term applied to a cross formed of the two ends of a ship's cable.

CABOCHED, in heraldry, is when the heads of beasts are borne without any part of the neck, full faced.

CABOLETTO, in commerce, a coin of the republic of Genoa, worth about three pence of our money.

CACALIA, in botany, Alpine colt's foot, a genus of the polygamia æqualis order, and syngenesia class of plants. The receptacle is naked; the pappus hairy; the calyx cylindrical, oblong, and calyced, or having a small calyx of very short scales only at the base. There are 33 species: the most remarkable are:

1. Cacalia ficoides, a native of the Cape of Good Hope. It rises with strong round stalks to the height of seven or eight feet. The flowers are in small umbels; they are white, tubulous, and cut into five parts at the top. The

leaves are pickled by the French, who esteem them much. They have a method of preserving the white farina upon them, which adds greatly to the beauty of the pickle when brought to table.

2. Cacalia kleinia, with a compound shrubby stalk. It grows naturally in the Canary islands, but has long been cultivated in the English gardens. There have been stones and fossils dug up at a very great depth in some parts of England having very perfect impressions of this plant upon them. This plant has been called the cabbage tree, from the resemblance which the stalk of it has to the cabbage. Others have entitled it carnation tree, from the shape of the leaves and the colour of the flowers.

CACHEXY, in medicine, such a disposition of the body as depraves the nourishment throughout its whole habit. See MEDICINE.

CACHRYS, a genus of the digynia order, and pentandria class of plants; and in the natural method ranking under the 45th order, umbellatæ. The fruit is subovate, angled, and cork or spongy rinded. There are five species, *viz.*

1. Cachrys hungarica, with a plain, fungous, channelled seed. 2. Cachrys libanotis, with smooth furrowed seeds. 3. Cachrys linearis, with plain channelled fruit. 4. Cachrys sicula, with double winged leaves. 5. Cachrys trifida, with bipinnated leaves. All these are perennial plants, rising pretty high, and bearing large umbels of yellow flowers, and may be propagated by seeds.

CACTUS, melon thistle: a genus of the monogynia order, and icosandria class of plants; and in the natural method ranking under the 13th order, succulentæ. The calyx is monophyllous, superior, or above the receptacle of the fruit, imbricated; the corolla polypetalous; the fruit an unilocular polyspermous berry. To this genus Linnæus has added the cereus and opuntia. See Plate XXIII. Nat. Hist. fig. 71. The cacti are plants of a singular structure. When the plants are cut through the middle, their inside is a soft, pale green, fleshy substance, very full of moisture. The fruits of all the species are frequently eaten by the inhabitants of the West Indies. They are about three fourths of an inch in length, of a taper form, drawing to a point at the bottom toward the plant, but blunt at the top, somewhat like a pear. The taste is agreeably acid, which in a hot country must render them grateful. There are 27 species, all natives of the West Indies. The two following are the most remarkable, *viz.* 1. Cactus cochenillifer, the species which the cochineal animals inhabit. See Coccus. 2. Cactus grandiflora, one of the creeping cereuses. The flower of this species, though very short lived, is as grand and beautiful as any in the vegetable system: it begins to open in the evening about seven o'clock, is in perfection about eleven, and fades about four in the morning; so that the same flower only continues in perfection about six hours. The calyx when expanded is about a foot in diameter, of a splendid yellow within, and a dark brown without; the petals are many, and of a pure white; and the great number of the recurved stamina, surrounding the style in the centre of the flower, make a grand appearance, to which may be added the fine scent which perfumes the air to a considerable distance. It flowers in July.

The cactus tribe are divided by gardeners into, 1. melon thistles or turks caps; 2. torch thistles; 3. creeping cereuses; 4. Indian figs or prickly pears. The cochineal plant is of this last description. They are easily distinguished from the euphorbia by the milky juice which exudes from the latter on puncture.

CADE, a cag, cask, or barrel. A cade of herrings is a vessel containing the quantity of 500 red herrings, or of sprats 1000.

CADENE, one of the sorts of carpets which the Europeans import from the Levant. They are the worst sort of all, and are sold by the piece from one to two piasters per carpet.

CADI, or CADHI, a judge of the civil affairs in the Turkish empire. It is generally taken for the judge of a town, judges of provinces being distinguished by the appellation of mouls.

In Biledulgerid in Africa, the cadi decides in spiritual affairs.

CADILESCHER, a principal officer of justice among the Turks, answering to a chief justice among us.

CADRITES, Mohammedan friars, who once a week spend great part of the night in turning round, holding each other's hands, and repeating incessantly the word *hai*, which signifies living, and is one of the attributes of God; during which one of them plays on a flute.

CÆCILIA, the name of a genus of serpents. The generic character is, that the body is without scales, is smooth, and moves by means of lateral rugæ or wrinkles; the upper lip is prominent, and furnished with two tentacula; it has no tail. There are three species, *viz.*

1. Cæcilia tentaculata. Eel shaped cæcilia. The length of this species is about a foot, and its general appearance that of a small eel: its colour a livid brown, the abdomen paler or whitish: is a native of South America, and is said to be of an innoxious nature.

2. Cæcilia glutinosa. White sided cæcilia. Is about the same length and diameter with the former, but has a large tumid head, and wider nostrils, without any appearance of tentacula: the colour of both head and body is deep brown, and along each side runs a broad whitish stripe; the wrinkles are extremely close and numerous, and disposed in such a manner as to form a slight carina along the sides on the white stripe. This is a native of South America.

3. Slender cæcilia. Length 13 inches and three quarters: diameter, which is perfectly equal throughout, one fifth of an inch: skin smooth, but when closely examined appearing most minutely granulated. It is supposed to be a native of South America.

CÆCUM, or CŒCUM, in anatomy, the blind gut, or first of the thick intestines. See ANATOMY.

CÆRITES, or CÆRITUM TABULÆ, in Roman antiquity, tables or registers in which the names of the Cærites were registered. The people of Cære were accounted citizens of Rome, but had no privilege of voting. Hence when a Roman citizen was degraded, if a senator, he was expelled the senate; if a knight, he lost the public horse; and if a plebeian, his name was inserted in the register of the Cærites; that is, he was subject to all taxes, but incapable of voting or enjoying any public office.

CÆSALPINIA, BRASILETTO, or BRAZIL WOOD, a genus of the decandria class, and monogynia order of plants; and in the natural method ranking under the 33d

order, lomentaceæ. The calyx is quinquefid, with the lowest segment larger in proportion. There are five petals, the lowest most beautiful. It is a leguminous plant. There are eight species, the most remarkable of which is:

Cæsalpinia brasiliensis, commonly called brasiletto. It grows naturally in the warmest parts of America, whence the wood is imported for the dyers. The demand has been so great, that none of the large trees are left in any of the British plantations; so that Mr. Catesby owns himself ignorant of the dimensions to which they grow. The largest remaining are not above two inches in thickness, and eight or nine feet in height. The branches are slender, and full of small prickles; the leaves are pinnated; the lobes growing opposite to one another, broad at their ends, with one notch. The flowers are white, papilionaceous, with many stamina and yellow apices, growing in a pyramidal spike at the end of a long slender stalk: the pods enclose several small round seeds. The colour produced from this wood is greatly improved by a solution of tin in aqua regia. There is another sort, a native of the same countries with the first, but of a larger size. It sends out many weak irregular branches, armed with short, strong, upright thorns. The flowers are produced in long spikes like those of the former, but are variegated with red. These plants may be propagated from seeds, and should be constantly kept in the stove.

CÆSARIAN SECTION. See MIDWIFERY.

CÆSTUS, in antiquity, a large gauntlet made of raw hide, which the wrestlers made use of when they fought at the public games. It was a kind of leathern strap, strengthened with lead, or plates of iron, which encompassed the hand, the wrist, and a part of the arm, as well to defend these parts as to enforce their blows.

CÆSURA, in the ancient poetry, is when, in the scanning of a verse, a word is divided so that one part seems cut off, and goes to a different foot from the rest; as,

Menti | ri no | li, nun | quam men | dacia | prosunt:

where the syllables ri, li, quam, and men, are cæsuras.

CAFFA, in commerce, painted cotton cloths manufactured in the East Indies, and sold at Bengal.

CAFFILA, a company of merchants or travellers, who join together in order to go with more security through the dominions of the great mogul, and through other countries on the continent of the East Indies. The caffila differs from a caravan, at least in Persia; for the caffila belongs properly to some sovereign, or to some powerful company, of Europe; whereas a caravan is a company of particular merchants, each trading upon his own account. The English and Dutch have each of them their caffila at Gambron.

CAG, or KEG, of sturgeon, &c. a cask or vessel that contains from four to five gallons.

CAHYS, a dry measure for corn, used in some parts of Spain, particularly at Seville and at Cadiz. It is nearly a bushel of our measure.

CAIC, or CAIQUE, a skiff, or sloop, belonging to a galley. The same name is given to a small kind of bark used in the navigation of the Black Sea, and carrying from 40 to 50 men. Those used on the sea of Marmora are generally manned by two or three rowers, and they are incessantly employed in crossing the harbour, and proceeding to the several neighbouring villages and islands. They carry one or more sails, which are set only in fair weather, and when the wind is not strong.

CAIMACAN, or CAIMACAM, in the Turkish affairs, a dignity in the Ottoman empire, answering to lieutenant, or rather deputy, among us.

CAINIANS, or CAINITES, in church history, a Christian sect that sprung up about the year 130, and took their name from Cain, whom they looked upon as their head and father. They said that he was formed by a celestial and almighty power, and that Abel was made but by a weak one.

CAISSON, in the military art, a wooden chest, into which several bombs are put, and sometimes only filled with gunpowder. This is buried under some work, of which the enemy intend to possess themselves; and when they are masters of it, is fired, in order to blow them up. It is also employed for a wooden frame, or chest, used in laying the foundations of the piers of a bridge.

Caissons were used in the building of Westminster bridge, each of which contained 150 loads of fir timber, and was of more tonnage than a 40 gun frigate: their size was 80 feet long, and 30 feet broad, and their sides 10 feet in height. The caisson was provided with a sluice to admit the water. The method of working was as follows: a pit being dug, and levelled in the proper situation for the pier, of the same shape as the caisson, only larger, it was brought to its position, and a few of the lower courses of the pier built in it, and sunk once or twice, to prove the level of the foundation; then being finally fixed, the masons worked in the usual way of tide work. About two hours before low water, the sluice was shut down, and the water pumped out, for the masons to set and cramp the stone work of the succeeding courses. In this manner the work proceeded till the pier rose to the surface of the caisson, when the sides were floated away to serve the same purpose at another pier.

CAKILE maritima, sea rocket, in botany, a plant of the class tetradynamia, order siliculosæ. The character is, cal. 4 leaved spreading; cor. 4 petaled; colour white and purple; small pod lanceolate; flowers in June: a native of New Jersey and Carolina. (*a*)

CALADIUM, sagittæ folium, arrow leaved caladium, in botany, a plant of the class monoecia, order polyandria. The cal. spatha, cor. none; pericarpium one celled, containing many seeds; flourishes in Georgia. (*a*)

CALAMANCO, a sort of woollen stuff manufactured in England and in Brabant. It has a fine gloss, and is checkered in the warp, whence the checks appear only on the right side. Some calamancoes are quite plain, others have broad stripes adorned with flowers, some with plain broad stripes, some with narrow stripes, and others watered.

CALAMINARIS, or LAPIS CALAMINARIS, in natural history, an ore of zinc, of a spongy substance, and a lax and cavernous texture, yet considerably heavy. See ZINC.

CALAMUS, a genus of the monogynia order, and hexandria class of plants; and in the natural method ranking under the 5th order, tripetaloideæ. The calyx is hexaphyllous, there is no corolla, the fruit is a dry monospermous berry, imbricated backward. There is but one species, *viz.*

Calamus rotang. The stem is without branches, has a crown at top, and is every where beset with straight

spines. This is the true Indian cane, which is not apparently such on the outside; but the external bark being taken off discovers the smooth stick, which has no marks of spine on the inner bark; and is exactly like those which the Dutch sell to us, keeping this matter very secret, lest travellers going by should take as many canes out of the woods as they please. Sumatra is said to be the place where most of these sticks grow. Such are to be chosen as are of proper growth, between two joints, suitable to the fashionable length of canes as they were then used; but such are scarce. The calamus rotang is one of several plants from which the drug called dragon's blood is obtained. See Plate XXIII. Nat. Hist. fig. 72.

Calamus aromaticus. See Acorus.

CALATOR, in antiquity, was a public servant, and a freeman, such as a bailiff or crier, or summoner, to summon courts, synods, and other public assemblies.

CALATRAVA, *knights of*, a military order in Spain, instituted under Sancho III. king of Castile, upon the following occasion. When that prince took the strong fort of Calatrava from the Moors of Andalusia, he gave it to the Templars; who, wanting courage to defend it, returned it to him again. Then don Raymond, of the order of the Cistercians, accompanied with several persons of quality, made an offer to defend the place, which the king thereupon delivered up to them, and instituted that order.

CALCANEUM, or os calcis. See Anatomy.

CALCINATION, in chymistry, such a management of bodies by fire as renders them reducible to a calx or cinder.

As most metals were reducible to this form, the term calces of metals was long appropriated to them; but in science the term is supplanted by the characteristic appellation of oxide, which expresses the peculiar change that occurs in calcining metallic bodies by the absorption of oxygen. Calcination and oxidation are not strictly synonymous, even when applied to metals, since the true sense of the former implies the agency of fire, but the metals may be oxidated by the action of the acids as well as by heat and air.

CALCULI, Biliary, are hard bodies sometimes formed in the gall bladder, or in the duct through which the bile passes into the intestinal canal, and stop up the passage altogether. They naturally drew the attention of physicians, because it was soon ascertained that they occasioned the disease called jaundice. Accordingly they were examined and described by different chymists, and the facts ascertained before 1764 were collected by Haller in the sixth volume of his Physiology. Since that period, a treatise has been published on them by Vicq d'Azyr; and several new facts have been discovered by Poulletier de la Sale, Fourcroy, Gren, and Saunders.

Such of the biliary calculi as have been hitherto examined with attention may be arranged under four classes.

1. The first kind comprehends those which have a white colour, and a crystalized, shining, lamellated structure.

2. The second is brown coloured, and has the appearance of inspissated bile.

3. The third class comprehends those calculi which are composed of a mixture of the substances which constitute the two last.

4. The fourth comprehends those gall stones which do not flame, but gradually waste away at a red heat.

Let us take a view of each of these classes of biliary calculi.

1. The first species of biliary calculi was pointed out for the first time by Haller, in a dissertation published in 1749. Walther afterward added several new facts; and at last it was accurately described by Vicq d'Azyr. It is almost always of an oval shape, sometimes as large as a pigeon's egg, but commonly about the size of a sparrow's; and for the most part only one calculus, when of this species, is found in the gall bladder at a time. It has a white colour, and when broken presents crystaline plates or striæ, brilliant and white like mica, and having a soft greasy feel. Sometimes its colour is yellow or greenish; and it has constantly a nucleus of inspissated bile. Its specific gravity is inferior to that of water. Gren found the specific gravity of one 0.803.

When exposed to a heat considerably greater than that of boiling water, this crystalized calculus softens and melts, and crystalizes again when the temperature is lowered. It is altogether insoluble in water; but hot alcohol dissolves it with facility. Alcohol, of the temperature of 167°, dissolves $\frac{1}{20}$ of its weight of this substance; but alcohol, at the temperature of 60°, scarcely dissolves any of it. As the alcohol cools, the matter is deposited in brilliant plates resembling talc or boracic acid It is soluble in oil of turpentine. When melted it has the appearance of oil, and exhales the odour of melted wax: when suddenly heated it evaporates altogether in a thick smoke. It is soluble in pure alkalies, and the solution has all the properties of a soap. Nitric acid also dissolves it; but it is precipitated unaltered by water.

This matter, which is evidently the same with the crystals which Cadet obtained from bile, and which he considered as analogous to sugar of milk, has a strong resemblance to spermaceti. Like that substance, it is of an oily nature, and inflammable; but it differs from it in a variety of particulars.

Since it is contained in bile, it is not difficult to see how it may crystalize in the gall bladder if it happens to be more abundant than usual; and the consequence must be a gall stone of this species. Fourcroy found a quantity of the same substance in the dried human liver.

2. The second species of biliary calculus is of a round or polygonal shape, often of a gray colour externally, and brown within. It is formed of concentric layers of a matter which seems to be inspissated bile; and there is usually a nucleus of the white crystaline matter at the centre. For the most part there are many of this species of calculus in the gall bladder together; indeed it is frequently filled with them. The calculi belonging to this species are often light and friable, and of a brownish red colour. The gall stones of oxen, used by painters, belong to this species.

3. The third species of calculi are most numerous of all. Their colour is often deep brown or green; and when broken, a number of spermaceti crystals are observable, mixed with the inspissated bile.

The calculi belonging to these three species are soluble in alkalies, in soap lyes, in alcohol, and in oils.

4. Concerning the fourth species of gall stone, very little is known with accuracy. Dr. Saunders tells us that

he has met with some gall stones insoluble both in alcohol and oil of turpentine; some of which do not flame, but become red, and consume to an ash like a charcoal. Haller quotes several examples of similar calculi.

Gall stones often occur in the inferior animals, particularly in cows and hogs; but the biliary concretions of these animals have not hitherto been examined with much attention.

Calculi, *urinary.* It is well known that concretions not unfrequently form in the bladder, or the other urinary organs, and occasion one of the most dismal diseases to which the human species is liable.

These concretions were distinguished by the name of calculi, from a supposition that they are of a stony nature. They have long attracted the attention of chymists and physicians. Boyle extracted from calculi, by distillation, oil, and a quantity of volatile salts. Boerhaave supposed them compounds of oil and volatile salts. Slare attempted a chymical analysis of them. Hales extracted from them a prodigious quantity of air. He gave them the name of animal tartar, pointed out several circumstances in which they resemble common tartar, and made many experiments to find a solvent of them. Drs. Whytt and Alston pointed out alkalies as solvents of calculi. It was an attempt to discover a more perfect solvent that induced Dr. Black to make those experiments, which terminated in the discovery of the nature of the alkaline carbonates.

Such was the state of the chymical analysis of calculus, when, in 1776, Scheele published a dissertation on the subject in the Stockholm Transactions, which was succeeded by some remarks of Mr. Bergmann. These illustrious chymists completely removed the uncertainty which had hitherto hung over the subject, and ascertained the nature of the calculi which they examined. Since that time considerable additional light has been thrown upon the nature of these concretions by the labours of Austin, Walther, Brugnatelli, Pearson, &c. But the most important additions to our knowledge of calculi were made by Dr. Wollaston. That ingenious chymist distinguished them into species, and ascertained the composition of each, pointing out several new constituents which had not been suspected before.

Urinary calculi are usually spheroidal or egg shaped: sometimes they are polygonous, or resemble a cluster of mulberries; and in that case they are distinguished by the epithet mulberry. Their size is various; sometimes they are very small, and sometimes as large as a goose egg, or even larger. The colour of some of them is a deep brown, resembling that of wood. In some cases they are white, and not unlike chalk; in others, of a dark gray, and hard. These different colours are often intermixed, and occur of various degrees of intensity. Their surface in some cases is polished like marble; in others, rough and unequal; sometimes they are covered with semitransparent crystals. Their specific gravity varies from 1.213 to 1.976.

The substances hitherto discovered in urinary calculi are the following:

1. Uric acid,
2. Urat of ammonia,
3. Phosphate of lime,
4. Phosphate of magnesia and ammonia,
5. Oxalate of lime,
6. Carbonate of lime,
7. Silica,
8. Animal matter.

It appears from a strict analysis of the different urinary calculi, that all their component parts exist in urine, except oxalate of lime and silica. But little satisfactory is known concerning the manner in which they are formed, or of the cause of their formation. Whenever any solid body makes its way into the bladder, it has been observed that it is soon incrusted with a coat of phosphate of lime; and this first nucleus soon occasions a calculus. Concretions of uric acid seldom or never form in the bladder, unless a primitive nucleus has originated in the kidneys. The gravel, which is so frequently emitted by persons threatened with the stone, consists always of this acid. As oxalic acid does not exist in urine, some morbid change must take place in the urine when calculi composed of oxalate of lime are deposited.

As our ignorance of the cause of urinary concretions puts it out of our power to prevent their formation, the ingenuity of physicians has been employed in attempting to discover substances capable of dissolving them after they have formed, and thus to relieve the human race from one of the most dreadful diseases to which it is subject. These attempts must have been vain, or their success must have entirely depended upon chance, till the properties of the concretions themselves had been discovered, and the substances capable of dissolving them ascertained by experiment. We shall therefore pass over the numerous lithanthriptics which have been recommended in all ages, and satisfy ourselves with giving an account of the experiments made by Fourcroy and Vanquelin to dissolve stones by injections through the urethra, made after their analysis of the urinary calculi.

The component parts of urinary calculi, as far as solvents are concerned, may be reduced under three heads: 1. Uric acid and urat of ammonia: 2. the phosphates: 3. oxalate of lime.

1. A solution of pure potass and soda, so weak that it may be kept in the mouth, and even swallowed without pain, soon dissolves calculi composed of uric acid, or urat of ammonia, provided they are kept plunged in it.

2. The phosphates are very quickly dissolved by nitric or muriatic acid, so weak that it may be swallowed without inconvenience, and possessed of no greater acridness than urine itself.

3. Oxalate of lime is much more difficult of solution than the preceding substances. Calculi composed of it are slowly dissolved by nitric acid, or by carbonate of potass or soda, weak enough not to irritate the bladder; but the action of these substances is slow, and scarcely complete.

These solvents, injected into the bladder repeatedly, and retained in it as long as the patient can bear their action without inconvenience, ought to act upon the stone, and gradually dissolve it. The difficulty, however, is to determine the composition of the calculus to be acted upon, in order to know which of the solvents to employ. But as no method of deciding this point with certainty is at present known, we must try some one of the solvents for once or twice, and examine it after it has been thrown out of the bladder. Let us begin, for instance, with injecting a weak solution of potass; after it has remained in the

bladder half an hour, or longer if the patient can bear it, let the liquid, as soon as passed, be filtered and mixed with a little muriatic acid; if any uric acid has been dissolved, a white solution will make its appearance. This precipitate is a proof that the calculus is composed of uric acid. If it does not appear, after preserving in the alkaline solution for some days, then there is reason to expect the presence of the phosphates; of course a weak muriatic acid solution should be injected. After this solution is emitted, let it be mixed with ammonia, and the phosphate of lime will precipitate, if the calculus is composed of it. If neither of these solutions takes up any thing, and if the symptoms are not alleviated, we must have recourse to the action of nitric acid, on the supposition that the calculus is composed of oxalate of lime. These different solutions must be persisted in, and varied occasionally as they lose their efficacy, in order to dissolve the different coats of the calculus. Such are the methods pointed out by Fourcroy and Vauquelin. It is scarcely necessary to observe, that the bladder should be evacuated of urine previous to the injections, and that the injections should be previously heated to the temperature of the body.

CALCULUS, or *calculus humanus*, in medicine, the stone in the bladder or kidneys. See the preceding article.

Calculus *differentialis*, is a method of differencing quantities, that is, of finding an infinitely small quantity, which being taken an infinite number of times, shall be equal to a given quantity. An infinitely small quantity, or infinitesimal, is a portion of a quantity less than any assignable one; it is therefore accounted as nothing: and hence two quantities differing by an infinitesimal, are reputed equal. The word infinitesimal is merely respective, and implies a relation to another quantity: for example, in astronomy, the diameter of the earth is an infinitesimal in respect of the distance of the fixed stars. It must not, then, be confounded with any real being.

Infinitesimals are likewise called differentials, or differential quantities, when they are considered as the differences of two quantities. Sir Isaac Newton calls them momenta, considering them as momentary increments of quantities: for instance, of a line generated by the flux of a point, of a surface by the flux of a line, or of a solid by the flux of a surface. The calculus differentialis, therefore, and the doctrine of fluxions, are the same thing, under different names; the latter given by sir Isaac Newton, and the former by Mr. Leibnitz, who disputes with sir Isaac the honour of the discovery. There is, however, one difference between them, which consists in the manner of expressing the differentials of quantities: Mr. Leibnitz, and most foreigners, express them by the same letters as variable ones, prefixing only the letter d: thus the differential of x is called dx, and the differential of y, dy. And dx is a positive quantity if x continually increase, and a negative quantity if x decrease. We, on the other hand, following sir Isaac Newton, instead of dx, write $\dot{x}$, with a dot over it; and instead of dy, $\dot{y}$. But foreigners reckon this method not so commodious as the former, because if differentials were to be differenced again, the dots would occasion great confusion; not to mention that printers are more apt to overlook a point than a letter.

Now as permanent quantities are always expressed by the first letters of the alphabet, $da = 0$, $db = 0$, $dc = 0$; wherefore $d(x + y - a) = dx + dy$, and $d(x - y + a) = dx - dy$. The difference of quantities, then, is easily performed by the addition or subtraction of their compounds. To difference two quantities that multiply each other, as xy, multiply the differential of one factor into the other factor, and the sum of the two factors is the differential required. Thus the differentials of xy will be $xdy + ydx$, that is $d(xy) = xdy + ydx$. Again, if there be three quantities mutually multiplying each other, the factum of the two must be multiplied into the differential of the third; thus suppose vxy: let $vx = t$, and vxy will be $= ty$; consequently $d(vxy) = tdy + ydt$: but $dt = vdx + xdv$. If these values therefore are substituted in the antecedent differential $tdy + ydt$, it follows that $d(vxy) = vxdy + vydx + xydv$. In the same manner must we proceed when the quantities to be differenced are more than three. But if, while one variable quantity increases, the other, y, decreases, it is evident that $ydx - xdy$ will be the differential of xy.

The rule for differencing quantities that mutually divide each other, is first to multiply the differential of the divisor into the dividend; and, on the contrary, the differential of the dividend into the divisor. 2. To subtract the first product from the last. 3. To divide the remainder by the square of the divisor, and the quotient is the differential of the quantities mutually dividing each other. For instance, let $xy : vz$ be the quantities to be differenced: suppose $xy = t$, and $vz = w$; then $xy : vz$ will be equal to $t : w$. But $d(t : w) = (wdt - tdw) : w^2$; and $dt = xdy + ydx$, $dw = vdz + zdv$. Wherefore $d(t : w) = d(xy : vz) = (vzxdy + vzydx - xyvdz - xyzdv) : v^2z^2$. For a further account of the doctrine of the differentials, see Fluxions.

Calculus *exponentialis*, among mathematicians, a method of differencing exponential quantities. By an exponential quantity is meant a power, the exponent of which is variable, as x^x, a^x. In order to difference an exponential quantity, nothing else is required than to reduce the exponential quantities to logarithmic ones, upon which the differencing is managed as in logarithmic ones. For instance, suppose the differential of the exponential quantity x^y were required.

Let $x^y = z$

then will $ylx = lz$ $\quad lz = log.\ xz$

$lxdy + ydx : x :: dz : z$

$zlxdy + zydx = xdz.$

That is, $x^y\ lxdy + yx^{y-1}dx = dz$. If the exponential quantity to be differenced be of the second degree, as v^{x^y}, suppose as before

$$v^x = z$$

then will $x^y\ lv = lz$

$$\frac{(x^{y}\,lxdy + yx^{y-1}\,dx)\,lv + x^{y}\,dv : v = dz : z}{}$$

$$z\,(x^{y}\,lxdy + yx^{y-1}\,dx)\,lv + zx^{y}\,dv : v = dz$$

that is,

$$v^{x^{y}}\,(x^{y}\,lxdy + yx^{y-1}\,dx)\,lv + v^{x^{y}-1}\,v^{x^{y}}\,x^{y}\,dv + dz$$

or,

$$v^{x^{y}}\,x^{y}\,lxlvdy + v^{x^{y}}\,yx^{y-1}\,lvdx + v^{x^{y}-1}\,v^{x^{y}}\,x^{y}\,dv = dz.$$

By the same method may be found the differential of exponential quantity of any power. This calculus was invented by Mr. John Bernouilli, and is used in investigating the properties of exponential curves. See *Exponential* Curve.

Calculus *integralis*, or *summatorius*, is a method of summing up differential quantities; that is, from a differential quantity from whose differencing the given differential results.

It is the inverse of the calculus differentialis; whence the English, who usually call the differential method fluxions, give this calculus, which ascends from the fluxions to the flowing quantities, or, as Wolfius and other foreigners express it, from the differences to the sums, the name of the inverse method of fluxions.

Let s be the sign of the sum, or integral quantity, so that $sydx$ may denote the integral of the differential ydx. To integrate or sum up a differential quantity, 1. It is demonstrated that $sdx = x$. 2°. $s\,(dx \mp dy) = x \mp y$. 3°. $s\,(xdy + ydx) = xy$. 4°. $sm x^{m-1}\,dx = x^{m}$. 5°. $s\,(n - m) : m\;\; n : m\;\; x^{n-m}\,dx = x^{n}$. 6°. $s\,(ydx - xdy) : y^{2} = x : y$. Of these the fourth and fifth cases occur most frequently, in which the differential quantity is integrated, if a variable unity is added to the exponent, and the sum divided by the new exponent, multiplied into the differential of the root, as in the fourth case by $(m - 1 + 1)\,dx$, that is, by mdx.

If the differential quantity to be integrated, do not come under any of these formulas, it must either be reduced to an integrable finite, or an infinite series each of whose terms may be summed.

This calculus is applied to geometry, in the quadrature and rectification of curves, in cubing solids and measuring their surfaces, in the inverse method of tangents, and in the doctrine of logarithms.

It may be remarked, that as in the analysis of finites, any quantity may be raised to any given power; but, *vice versa*, the root cannot be extracted out of any number required: so in the analysis of infinites, any variable or flowing quantity may be differenced; but, *vice versa*, any differential cannot be integrated. And as in the analysis of finites, we are not yet arrived at a method of extracting roots of all equations, so neither has the integral calculus arrived at perfection: and as in the former we are obliged to have recourse to approximation, so in the latter we have recourse to a perfect integration. See Series.

Calculus, *antecedental*. A geometrical method of reasoning without any consideration of motion or velocity, applicable to every purpose to which fluxions have been or can be applied. It was invented by Mr. Glenie, who derived it from an examination of the antecedents of ratios, having given consequents, and a given standard of comparison in the several degrees of augmentation and diminution, which they undergo by composition and decomposition.

CALEA, in botany, a genus of the polygamia æqualis order and syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The receptacle is paleaceous, the pappus hairy, and the calyx imbricated. There are seven species.

CALENDAR. See Almanac.

The first calendar was made by Romulus, who divided the year into ten months only, beginning on the first day of March, and containing 304 days, in which time he imagined the sun performed his course through all the seasons. This calendar was reformed by Numa Pompilius, who added two months more, *viz.* January and February, placing them before March: his year began on the first of January, and consisted of 355 days. This was afterward improved by Julius Cæsar, and was by him called the Julian account, which reduced the year to 365 days, 6 hours; and was retained in most protestant countries, and in our nation till the year 1752. This year is disposed into quadriennial periods, whereof the first three years, which were called common, consisted of 365 days, and the fourth, bissextile, of 366. The Julian account was afterward corrected by pope Gregory XIII. which on that account obtained the name of the Gregorian calendar, or new style; the Julian being called the old style; and though the Gregorian calendar is preferable to the Julian, yet it is not without its defects.

When pope Gregory had reformed the calendar, he ordered all the ecclesiastics under his jurisdiction to conform to this new mode of reckoning; and he exhorted the Christian princes, within the pale of his authority, to adopt it in their dominions. It was accordingly introduced without delay into all catholic countries. In Spain, Portugal, and part of Italy, it was received on the same day as at Rome; but in France not till some months after. The catholic states in Germany adopted the Gregorian calendar in 1583; but the protestant states refused it. Hence arose a difference of 10, and afterward 11, days, between the methods of reckoning used in catholic and protestant countries. The protestant states in Germany reformed their calendar in 1700. But in this country the new style was not introduced till September, 1752; on the 2d of that month the old style ceased, and the next day was called the 14th, instead of the 3d. The act of parliament which altered the style changed also the beginning of the year from the 25th of March to the 1st of January.

Dr. Playfair, in his Chronology, has taken some pains to show that the method of intercalation used in the Gregorian calendar is not quite accurate. It supposes the tropical year to consist of 365 d. 5 h. 49′ 12″, whereas recent observations have shown it to be 365 d. 5 h. 48′ 45½″. The following intercalations ought to be made instead of those determined on by pope Gregory.

+	—	+	—	+	+	+	+	+
4	17	33	128	545	673	801	929	1057
—,	—,	—,	—,	—,	—,	—,	—,	—,
1	4	8	31	132	163	199	225	256

&c. so that one day is to be intercalated in the space of four years; or, more accurately, four days in 17 years; or still more accurately, eight days in 33 years, or 31 days in 128 years, and so on. The signs + and — indicate, that the number of intercalary days above which they are placed is too great or too small.

Julian Christian CALENDAR, that in which the days of the week are determined by the letters A, B, C, D, E, F, G; by means of the solar cycle, and the new and full moons, especially the paschal full moon, with the feast of Easter, and the other moveable feasts depending thereon, by means of golden numbers rightly disposed through the Julian year.

Gregorian CALENDAR, that which, by means of epacts rightly disposed, through the several months, determines the new and full moons, and the time of Easter, with the moveable feasts depending thereon, in the Gregorian year. Therefore the Gregorian calendar differs from the Julian, both in the form of the year, and in that epacts are substituted instead of golden numbers.

Reformed, or *corrected* CALENDAR, that which, setting aside golden numbers, epacts, and dominical letters, determines the equinox, with the paschal full moon, and the moveable feasts depending thereon, by astronomical computations, according to the Rudolphine tables.

CALENDER, a machine used in manufactories, to press certain woollen and silken stuffs, and linens, to make them smooth, even, and glossy, or to give them waves or water them, as may be seen in mohairs and tabbies. This instrument is composed of two thick cylinders, or rollers, of very hard and polished wood, round which the stuffs to be calendered are wound: these rollers are placed crosswise between two very thick boards, the lower serving as a fixed base, and the upper moveable, by means of a thick screw, with a rope fastened to a spindle, which makes its axis: the uppermost board is loaded with large stones cemented together, weighing 20,000 lb. or more. It is this weight that gives the polish, and makes the waves on the stuffs about the rollers, by means of a shallow indenture or engraving cut in it.

CALENDS, in Roman antiquity, the first day in each month, so called from the Greek καλειν, to proclaim; it being customary on those days to proclaim the number of holidays in each month. The Roman method of reckoning the days of their months has something extremely singular in it: instead of computing forward, in the natural order of the numbers 1, 2, 3, &c. they reckoned backward, in the manner expressed in the following verses:

Prima dies mensis cujusque est dicta *calendæ*;
Sex Maius, *nonas*, Julius, October, et Mars;
Quatuor at reliqui: habet *idus* quilibet octo;
Inde dies reliquos omnes die esse *calendas*;
Quas retro numerans, dices a mense sequente.

Hence, to find the day of our month answering to that of the calends, to the number of days in the preceding month add two, and from this sum subtracting the number of calends given, the remainder will be the day of our month: thus the fourth of the calends of June is found to answer to the 29th of May; and so on in other cases.

CALENDULA, in botany, the *marigold*, a genus of the polygamia necessaria order, in the syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The receptacle is naked, there is no pappus, the calyx is polyphyllous and equal, the seeds of the disk membranaceous. There are 14 species, none of them natives of Europe. The common kind is so well known as to need no description; and none of the others merit any, except

CALENDULA *fruticosa*, which in 1759 was introduced from the Cape of Good Hope. It has a slender shrubby perennial stalk, which rises to the height of seven or eight feet, but requires support. It may be propagated by cuttings.

CALIBER *compasses*, the name of a particular instrument used by gunners for measuring the diameters of shot, shells, &c. as also the cylinder of cannon, mortars, and howitzers. They resemble other compasses, except in their legs, which are arched, in order that the points may touch the extremities of the arch. To find the true diameter of a circle, they have a quadrant fastened to one leg, and passing through the other, marked with inches and parts, to express the diameter required: the length of each ruler or plate is usually between the limits of six inches and a foot. On these rulers are a variety of scales, tables, proportions, &c. such as are esteemed useful to be known by gunners. The following articles are on the completest gunner's callipers, *viz.* 1. The measure of convex diameters in inches. 2. Of concave ditto. 3. The weight of iron shot from given diameters. 4. The weight of iron shot from given gun bores. 5. The degrees of a semicircle. 6. The proportion of troy and avoirdupois weight. 7. The proportion of English and French feet and pounds. 8. Factors used in circular and spherical figures. 9. Tables of the specific gravity and weights of bodies. 10. Tables of the quantity of powder necessary for proof and service of brass and iron guns. 11. Rules for computing the number of shot or shells in a finished pile. 12. Rule concerning the fall of heavy bodies. 13. Rules for raising of water. 14. Rules for firing artillery and mortars. 15. A line of inches. 16. Logarithmetic scales of numbers, sines, versed sines, and tangents. 17. A sectoral line of equal parts, or the line of lines. 18. A sectoral line of plans and superficies. 19. A sectoral line of solids. See Plate XXIV.

CALIDUCT, in antiquity, a kind of pipes, or canals, disposed along the walls of houses and apartments, used by the ancients for conveying heat to several remote parts of the house from one common furnace.

CALIPH, the supreme ecclesiastical dignity among the Saracens; or, as it is otherwise defined, a sovereign dignity among the Mahometans, vested with absolute authority in all matters relating both to religion and policy. It signifies in the Arabic, successor or vicar: the Saracen princes assumed this title as descendants from Mahomet; the caliphs bearing the same relation to Mahomet that the popes pretend they do to Jesus Christ, or St. Peter. It is at this day one of the grand seignior's titles, as successor of Mahomet; and of the sophi of Persia, as successor of Ali.

CALIXTINS, in church history, a sect of Christians, in Bohemia and Moravia: the principal point in which they differed from the church, was the use of the chalice, or communicating in both kinds. Is is also a name given

to those, among the Lutherans, who follow the sentiments of George Calixtus, a celebrated divine, who opposed the opinion of St. Augustin on predestination, grace, and free will.

CALLA, *African*, or *Ethiopian arum*, a genus of the polyandria order, in the gynandria class of plants, and in the natural method ranking under the second order, piperitæ. The spatha is plain; the spadix covered with florets; there is no calyx; no petals; and the berries are monospermous.

There are four species, the most beautiful of which is the calla Æthiopica. It is a native of the Cape, and requires the shelter of a greenhouse. It propagates very easily by offsets. It resembles the arum, but the flower, or rather the spathe, is white.

CALLICARPA, a genus of the class and order tetrandria monogynia. The essential character is, calyx four cleft; corolla four cleft; berry four seeded.

There are seven species, trees and shrubs, of North America and the West Indies.

CALLICO, a kind of manufacture made of cotton. It takes it name from Callicut, a city on the coast of Malabar, where it was first manufactured. In the East Indies the callicoes are all painted by the hand, which is performed with great expedition. From these we derive our

Callico *printing*, which is the art of communicating different colours to particular spots or figures on the surface of the cloth, while the other parts retain its original whiteness. This art, or rather that to which we have just referred, has been practised in India for more than 2000 years. But in London callico printing was not introduced till about the year 1676, since which it has been encouraged by several acts of parliament.

This art consists in impregnating those parts of the cloth which are to receive a colour, with a mordant, and then dyeing it as usual with some dyestuff or other. The dyestuff attaches itself firmly only to that part of the cloth which has received the mordant. The whole surface of the cotton is indeed more or less tinged, but by washing, and bleaching it for some days on the grass with the wrong side uppermost, all the unmordanted parts resume their original colour, while those which have received the mordant retain it. Suppose that a piece of white cotton cloth is to receive red stripes; all the parts on which the stripes are to appear are pencilled over with a solution of acetite of alumina; after this, the cloth is dyed in the usual manner with madder. When taken out of the dyeing vessel, it is all of a red colour, but by washing and bleaching, the madder leaves every part of the cloth white, except the stripes impregnated with the acetite of alumina, which remain red. In the same manner may yellow stripes, or any other wished-for figure, be given to cloth, by substituting quercitron bark, weld, &c. for madder.

When different colours are to be given to different parts of the cloth at the same time, it is done by impregnating it with various mordants. Thus, if stripes are drawn upon a cotton cloth with acetite of alumina, and other stripes with acetite of iron, and the cloth afterward dyed in the usual way with madder, and then washed and bleached, it will be striped *red* and *brown*. The same mordants with quercitron bark, give *yellow* and *olive* or *drab*.

The mordants chiefly employed in callico printing are acetite of alumina, and acetite of iron. These mordants are applied to the cloth, either with a pencil, or by means of blocks, on which the pattern, according to which the cotton is to be printed, is cut. As they are applied only to particular parts of the cloth, care must be taken that none of them spread to the part of the cloth which is to be left white, and that they do not interfere with one another when several are applied. If these precautions are not attended to, all the elegance and beauty of the print must be destroyed. It is necessary, therefore, that the mordants should be of such a degree of consistence, that they will not spread beyond those parts of the cloth on which they are applied. This is done by thickening them with flour or starch, when they are to be applied by the block: and with gum-arabic, when they are to be put on by a pencil. The thickening should never be greater than is sufficient to prevent the spreading of the mordants; when carried too far, the cotton is apt not to be sufficiently saturated with the mordants; of course the dye takes but imperfectly.

In order that the parts of the cloth impregnated with mordants may be distinguished by their colour, it is usual to tinge the mordants with some colouring matter or other. The printers commonly use the decoction of Brazil wood for this purpose; but Dr. Bancroft has objected to this method, because he thinks that the Brazil wood colouring matter impedes the subsequent process of dyeing. It is certain that the colouring matter of the Brazil wood is displaced, during that operation, by the superior affinity of the dyestuff of the mordants. Was it not for this superior affinity, the colour would not take at all. Dr. Bancroft advises to colour the mordant with some of the dyestuff afterward to be applied; and he cautions the using of more for that purpose, than is sufficient to make the mordant distinguishable when applied to the cloth. The reason of this precaution is obvious. If too much dye is mixed with the mordant, a great proportion of the mordant will be combined with colouring matter, which must weaken its affinity for the cloth, and of course prevent it from combining with it in sufficient quantity to ensure a permanent dye.

Sometimes these two mordants are mixed together in different proportions; and sometimes one or both is mixed with an infusion of sumach, or of nutgalls. By these contrivances, a great variety of colours are produced by the same dyestuff.

After the mordants have been applied, the cloth must be completely dried. It is proper for this purpose to employ artificial heat, which will contribute something toward the separation of the acetous acid from its base, and toward its evaporation, by which the mordant will combine in a greater proportion, and more intimately with the cloth.

When the cloth is sufficiently dried, it is to be washed with warm water and cow dung, till all the flour, or gum, employed to thicken the mordants, and all those parts of the mordants which are uncombined with the cloth, are removed. The cow dung serves to entangle these loose parts of the mordants, and to prevent them from combining with those parts of the cloth which are to remain white. After this, the cloth is thoroughly rinsed in clean water.

Almost the only dyestuffs employed by callico printers, are indigo, madder, and quercitron bark, or weld. This last substance, however, is but little used by the printers of this country, except for delicate greenish yellows. The quercitron bark has almost superseded it, because it gives colours equally good, and is much cheaper and more convenient, not requiring so great a heat to fix it. Indigo, not requiring any mordant, is commonly applied at once, either with a block or a pencil. It is prepared by boiling together indigo and potash made caustic by quicklime, and orpiment; the solution is afterward thickened with gum. It must be carefully secluded from the air, otherwise the indigo would soon be regenerated, which would render the solution useless. Dr. Bancroft has proposed to substitute coarse brown sugar for orpiments: it is equally efficacious in decomposing the indigo, and rendering it soluble; while it likewise serves all the purposes of gum.

Let us now give an example or two of the manner in which the printers give particular colours to callicoes. Some callicoes are only printed of one colour, others have two, others three or more, even to the number of eight, ten, or twelve. The smaller the number of colours, the fewer in general are the processes.

1. One of the most common colours on cotton prints, is a kind of nankeen yellow of various shades down to a deep yellowish brown, or drab. It is usually in stripes or spots. To produce it the printers besmear a block, cut out into the figure of the print, with acetite of iron, thickened with gum or flour; and apply it to the cotton, which, after being dried and cleaned in the usual manner, is plunged into a potash lye. The quantity of acetite of iron is always proportioned to the depth of the shade. 2. For yellow the block is besmeared with acetite of alumina. The cloth, after receiving this mordant, is dyed with quercitron bark, and then bleached. 3. Red is communicated by the same process; only madder is substituted for the bark. 4. The fine light blues which appear so often on printed cottons, are produced by applying to the cloth, a block besmeared with a composition, consisting partly of wax, which covers all those parts of the cloth which are to remain white. The cloth is then dyed in a cold indigo vat; and after it is dry, the wax composition is removed by hot water. 5. Lilac, flea brown, and blackish brown, are given by means of acetite of iron; the quantity of which is always proportioned to the depth of the shade. For very deep colours, a little sumach is added. The cotton is afterward dyed in the usual manner with madder, and then bleached. 6. Dove colour and drab, by acetite of iron, and quercitron bark.

When different colours are to appear in the same print, a greater number of operations are necessary. Two or more blocks are employed, upon each of which, that part of the print only is cut, which is to be of some particular colour. These are besmeared with different mordants and applied to the cloth, which is afterward dyed as usual. Let us suppose, for instance, that these blocks are applied to cotton, one with acetite of alumina, another with acetite of iron, a third with a mixture of those two mordants, and that the cotton is then dyed with quercitron bark, and bleached. The parts impregnated with the mordants would have the following colours.

Acetite of alumine,	Yellow.
——-—— iron,	Olive, drab, dove.
The mixture,	Olive green, olive.

If part of the yellow is covered over with the indigo liquor, applied with a pencil, it will be converted into *green*. By the same liquid, blue may be given to such parts of the print as require it.

If the cotton is dyed with madder, instead of quercitron bark, the print will exhibit the following colours.

Acetite of alumine,	Red.
———— iron,	Brown, black.
The mixture,	Purple.

When a great number of colours are to appear; for instance, when those communicated by bark, and those by madder, are wanted at the same time; mordants for part of the pattern are to be applied; the cotton is then to be dyed in the madder bath, and bleached: then the rest of the mordants, to fill up the pattern, are added, and the cloth is again dyed with quercitron bark, and bleached. The second dyeing does not much affect the madder colours; because the mordants, which render them permanent, are already saturated. The yellow tinge is easily removed by the subsequent bleaching. Sometimes a new mordant is also applied to some of the madder colours, in consequence of which, they receive a new permanent colour from the bark. After the last bleaching, new colours may be added by means of the indigo liquor. The following table will give an idea of the colours, which may be given to cotton by these complicated processes.

I. *Madder dye.*

	Colours.
Acetite of alumine,	Red.
——-—— iron,	Brown, black.
——-—— diluted,	Lilac.
Both, mixed,	Purple.

II. *Bark dye.*

Acetite of alumine,	Yellow.
——-—— iron,	Dove, drab.
Lilac and acetite of alumine,	Olive.
Red and acetite of alumine,	Orange.

III. *Indigo dye.*

Indigo,	Blue.
Indigo and yellow,	Green.

Thus no less than 12 colours may be made to appear together in the same print, by these different processes.

These instances will serve to give the reader an idea of the nature of callico printing, and at the same time afford an excellent illustration of the importance of mordants in dyeing.

If it was possible to procure colours sufficiently permanent, by applying them at once to the cloth by the block or the pencil, as is the case with the mordants, the art of callico printing would be brought to the greatest possible simplicity; but at present, this can only be done in one case, that of indigo; every other colour requires dyeing. Compositions, indeed, may be made, by previously combining the dyestuff and the mordants. Thus *yellow* may be applied at once, by employing a mixture of the infusion

of quercitron bark and acetite of alumine; *red*, by mixing the same mordant with the decoction of alumine, and so on. The colours applied in this way are, unfortunately, far inferior in permanency to those produced when the mordant is previously combined with the cloth, and the dyestuff afterward applied separately. In this way are applied almost all the fugitive colours of callicoes, which washing, or even exposure to the air, destroys. As the application of colours in this way cannot always be avoided by callico printers, every method of rendering them more permanent is an object of importance.

CALLIGONUM, in botany, a genus of the polyandria digynia class of plants, having no flower; the fruit is an oval, compressed, striated, hairy pericarpium, with bifid tops, turning backward; the seed is single. There are three species.

CALLISIA, in botany, a genus of the monogynia order, in the triandria class of plants, and in the natural method ranking under the 6th order, ensatæ. The calyx is triphyllous; the petals are three; the antheræ are double; and the capsule is bilocular. There is but one species, a native of America.

CALLITRICHE, or *star grass*, in botany, a genus of the digynia order, in the monandria class of plants, and in the natural method ranking under the 12th order, holoraceæ. It has no calyx, but two petals, and the capsule is bilocular and tetraspermous. There are two species.

CALLUS, or *callosity*, any cutaneous, corneous, or osseous hardness, whether natural or preternatural: but most frequently it means the callus generated about the edges of a fracture, provided by nature to preserve the fractured bones, or divided parts, in the situation in which they are replaced by the surgeon. See SURGERY.

CALODENDRUM, a genus of the class and order pentandria monogynia. The essential character is, calyx spreading, five petaled; nect. five leaved; capsule five celled. There is one species, a native of the Cape.

CALOGERI, in church history, monks of the Greek church, divided into three degrees: the novices, called archari; the ordinary professed, called microchemi; and the more perfect, called megalochemi: they are likewise divided into cœnobites, anchorets, and recluses. The cœnobites are employed in reciting their office from midnight to sunset. The anchorets retire from the conversation of the world, and live in hermitages, in the neighbourhood of the monasteries; they cultivate a little spot of ground, and never go out but on Sundays and holidays to perform their devotions at the next monastery. As for the recluse, they shut themselves up in grottoes and caverns, on the tops of mountains, from which they never go out, abandoning themselves entirely to Providence. They live on the alms sent them by the neighbouring monasteries.

CALOMEL. See MATERIA MEDICA.

CALOPHYLLUM, in botany, a genus of the polyandria monogynia class of plants, whose corolla consists of four roundish, hollow, patent petals, and is larger than the cup; the fruit is a large globose drupe. There are two species.

CALORIC, a word used to denote that substance by which the phenomena of heat are produced.

Philosophers formerly differed in opinion respecting the causes of those phenomena; and there were many who considered them merely as the effect of the mechanical changes of bodies, and some even admitted an active principle of cold. At present, however, it is almost unanimously agreed, that these effects are produced by a peculiar matter which has received the name of caloric; and which, in general, enables us to explain those appearances fully, and in a satisfactory manner. Caloric is an unconfinable fluid, highly elastic, and so very subtle that its gravity has not yet been ascertained. It is diffused through all natural bodies, with which it is more or less combined, according as their affinities for it are greater or less. We are not acquainted with any body that does not enter into combination with it; nor any from which the utmost endeavours could entirely separate it: and caloric, therefore, is not to be had in a pure state in nature: hence chymists, when mentioning the constituent parts of bodies, pay no regard to the presence of caloric, but consider it as understood of course. All bodies are combined in some way with a certain portion of caloric; or, to express it in other words, the particles of every substance are intermixed in a variable proportion with the particles of caloric, and kept probably apart by them. Hence the elementary particles of bodies do not, in fact, touch each other; and this is manifest from the property which all bodies possess, of being contracted into a lesser volume when deprived of heat. See PYROMETER.

Caloric, being a substance perfectly elastic, whose component particles would expand ad infinitum if not impeded, all bodies combined with them ought likewise to expand ad infinitum, if there existed no power which acted in direct opposition to its elasticity. This power is the mutual attraction of the particles, or cohesion. All material bodies, therefore, are continually acted upon by two powers, which tend more or less to equipoise each other; one causes the particles of bodies to recede from each other, and by the other they tend to approximate.

The proportion of each of these powers determines the exterior form of bodies. If cohesion predominates, then the bodies are solid; but if this power be overcome, then the particles are further removed, and their volume is proportionally increased. Finally, if caloric predominates to such a degree that the particles of bodies are placed out of the sphere of their reciprocal attraction, they lose their aggregation, and appear no longer in the form of solids, but become liquid or gaseous.

But if there existed no other power but the two already mentioned, bodies would not remain liquid; for, on increasing the heat, they would immediately pass from the solid to the aeriform, or gaseous state. But there is a third power, which, by acting at the same time, preserves them in an intermediate or liquid state. This power is the pressure of the atmosphere, without which there would be no liquid in nature, for all bodies would be either solid or aeriform. Hence all bodies, from their combination with caloric, may exist in three different states, which result from, 1. The power of attraction by which bodies cohere. 2. The quantity of caloric with which the substance is combined. 3. The greater or less pressure of the atmosphere.

The means by which a solid body may be changed into a liquid are, therefore: 1. A combination with a new and sufficient quantity of caloric, and 2. An union with another body already liquid. The operation by which a body

is rendered liquid, according to the first method, is termed fusion, the theory of which is clear from what has been advanced. In the second case, a body becomes liquid, if the quantity of caloric, in the liquid body added, be sufficient to remove the elementary particles of the new compound, to such a distance as will enable them to move freely in all directions.

A liquid body is rendered solid, 1. By the loss of a portion of its caloric. 2. By combining it with another solid body. In the former case, a body parts with that portion of caloric whereby it overcame the repelling force of the molecules, which now approach nearer to each other; so that they are again acted upon by cohesion. This change of bodies is termed congelation. In the latter case, the compound body becomes solid, if the caloric, present in the liquid, be not sufficient to prevent the attraction of the constituent particles of the new body, so as to cause it to be acted upon by cohesion.

A liquid is changed into the state of gas, 1. By being combined with a quantity of caloric sufficient to equipoise the pressure of the atmosphere. 2. If the pressure of the atmosphere is either sufficiently diminished, or totally removed.

A gas becomes liquid, 1. By the loss of that superabundant portion of caloric which resisted the pressure of the atmosphere. 2. By sufficiently increasing that pressure. Hence in every elastic fluid, two principal objects are to be considered: first, the caloric which gives its exterior form, *viz.* that of gas. Secondly, the body dissolved by the caloric, and by which the peculiar chymical properties of the gas are determined. This latter is generally termed the base, which we must be cautious not to confound with the gas itself.

Caloric continually tends to form an equilibrium. Hence it is, that, if two bodies of the same nature; for instance, two pieces of the same metal; be unequally heated, or imbued with different portions of caloric, and brought into contact with each other, the caloric equally diffuses itself throughout the two bodies; and the quantities of caloric, in each body, will bear the same proportion to each other as the masses themselves. But, supposing the two bodies to be of a different kind, in that case, though the caloric would also form an equilibrium, and each body would indicate the same temperature to the thermometer, yet the proportions of caloric in each body, will not be as the masses, but will vary according as the bodies differ. This property of bodies, to require different quantities of caloric to indicate the same temperature to the thermometer, was termed by Dr. Black, the capacity of a body for heat; but the quantity of caloric itself he called specific heat. The cause of this phenomenon arises from the different degrees of affinity which different bodies possess for caloric, and from which the capacities, and various points of saturation, of different bodies may be estimated.

When any body is in equilibrio with the bodies which surround it, with respect to its caloric, that quantity which it contains is not perceptible by any external sign or organ of sense, and is termed combined caloric, or, according to Black, latent heat. But, if the latent heat, from any cause, is forced, in some degree, to quit a body, and to combine with those that surround it, then such caloric is said to be free or sensible until the equilibrium is restored.

It is this caloric in a free state which acts upon our organs, and excites that sensation which we term warmth; and it is this alone which we can ascertain by the thermometer. The temperature of a body is, therefore, the termination of the rarefaction of the mercury, at the instant when its caloric has established an equilibrium with that of the body.

The equilibrium of caloric is destroyed by the following causes: 1. A change of the capacities in bodies by chymical analysis or synthesis. 2. External mechanical pressure. As to the former, the reason of the separation or addition of caloric is to be sought for from the general laws of chymical composition, *viz.* that a compound body possesses properties different from its constituent parts. Hence the capacity of the compound body is not always a mean between the sum of the capacities of its constituent parts, but is oftentimes greater or less; and, on account of this greater or less capacity of a compound body, caloric, at the moment the constituent parts unite, is either expelled or attracted from surrounding bodies. In the former case, the temperature of the surrounding bodies is increased, in the latter it is diminished. When a body, whose temperature has been raised, comes into contact with several other bodies of lower temperatures, then the caloric endeavours to form an equilibrium; and that of the first body, because it is this especially which causes a change in the equilibrium, diffuses itself throughout the second, and thence throughout the third, and so in succession till all their temperatures are equal. The intermediate bodies, through which caloric permeates, are called conductors of heat; and as they convey it more or less quickly, they are said to be good or bad conductors. All bodies possess the property of communicating caloric, but according to different degrees, being hence termed good or bad conductors. Hitherto we know of but one exception, which is in congealed water or ice. This body imbibes all the caloric which it receives from other bodies; nor does it communicate the least quantity to such as lie contiguous to it, until the quantity of caloric it has absorbed has rendered it liquid. The water produced follows again the general law, and becomes a conductor of heat. Therefore, if a body of a certain temperature is brought into contact with ice, it will impart to the ice its own caloric, till it has descended to the temperature of the ice itself; and we shall see that only as much of the ice returns to the state of water as the caloric, which it had imbibed, could liquefy. This, however, is that portion of caloric, which had raised the body from the temperature of the ice to that which it possessed previously to the experiment, and which we have denominated specific heat. Moreover, since equal quantities of caloric ought to liquefy equal quantities of ice, it follows, that the specific heat of bodies, under like circumstances, is in a direct ratio of the quantities of ice which they can liquefy when brought into contact.

From the foregoing observations we may draw the following conclusions:

1. If equal quantities of the same body, at the same temperature, come severally into contact with ice, then equal quantities of ice will be changed into the liquid state of

water, and such bodies will descend to the temperature of the ice.

2. If unequal quantities of the same body are treated in a similar manner, then the quantities of the ice liquefied will be in a direct ratio of the quantities of the body.

3. But, if equal quantities of different bodies are treated in this way, then the quantities of the ice liquefied will be in a direct ratio of the quantities of caloric which those bodies have lost; or, in other words, they will be in a direct ratio of the quantities of caloric which caused those bodies to ascend from the temperature of the ice to that which they possessed at the beginning of the experiment: and therefore, as the masses of the bodies were equal, they will be in a direct ratio of their specific heat, and in a direct ratio of their own capacities for caloric.

These experiments not only demonstrate, that different bodies, in reality, possess different capacities for caloric; but they likewise show us the means by which we are enabled to measure the relative quantities which they contain.

Heat and cold, with respect to our senses, are distinguished by those perceptions which are the effect either of an augmentation, or diminution of caloric, in the animal body, whenever we approach an object whose temperature is either higher or lower than that which we ourselves possess. But the perception is always modified by the state of the organs, and the temperature they have been before exposed to. Hence not only one person shall feel cold, another warm, in the same atmosphere; but if we plunge our hands for some time, the one into hot, the other into cold water, and suddenly transfer them both into water of the heat of the blood, the same water will distinctly impress on our perceptions both heat and cold. It follows, that our perceptions are not a just criterion of the state of bodies as to their temperature.

Incandescence and flame are observed in the rapid disengagement of caloric and light. The first effect of this disengagement is inflammation; and these phenomena, taken collectively, excite in us that idea which is expressed by the word fire.

Among the various states of heat, it is necessary that we should consider caloric in two points of view. First, as it elevates bodies above the temperature of the surrounding medium, where it is known by the term sensible heat, and which we can measure either by a common thermometer, or by Wedgewood's pyrometer. Secondly, the whole quantity of caloric existing in a body in chymical union, where it is known by the term absolute heat, the quantity of which is ascertained by the calorimeter of La Place. From the principal laws which caloric follows in its combination with other bodies, and from the properties already recited, many phenomena may be explained which occur in the chymical solution of bodies, and in which caloric is the principal agent. Thus: 1. Why two solid bodies cannot mutually dissolve each other; and why it is necessary, for that purpose, that one of them, at least, should be in a fluid state. 2. Why, in most combinations of solids with fluids, caloric promotes solution. 3. Why the contrary happens in solutions of aeriform bodies in liquids. 4. Why the combination of two solid or two fluid bodies, or the combination of one fluid with one solid, produces a body which is either solid or fluid. 5. What phenomena ought to be produced as to volume, specific gravity, and temperatures.

CALOTTE, in architecture, a round cavity or depressure, in form of a cap or cup, lathed and plastered, used to diminish the rise or elevation of a moderate chapel, cabinet, alcove, &c. which, without such an expedient, would be too high for other pieces of the apartment.

CALTHA, *marsh marigold*, in botany, a genus of the polyandria polygynia class of plants, and in the natural method ranking under the 26th order, multisiliquæ. There is no calyx; there are five petals; no nectaria; the capsules are many and polyspermous. There is only one species known, which grows naturally in moist boggy lands in many parts of England. There is a variety with double flowers, which for its beauty is preserved in gardens. It is propagated by parting the roots in autumn. Upon May day the country people strew the flowers upon the pavement before their doors. Goats and sheep eat this plant; horses, cows, and swine, refuse it.

CALVARY, in heraldry, a cross; so called because it resembles the cross on which our Saviour suffered.

CALVINISTS, in church history, those who follow the opinions of John Calvin, one of the principal reformers of the church in the 16th century, a person of great parts and industry, and of considerable learning; whose doctrine still subsists in its greatest purity at Geneva, where it was first introduced, and whence it was propagated. The Calvinists are great advocates for the absoluteness of God's decrees; and hold that election and reprobation depend on the mere will of God, without any regard to the merit or demerit of mankind; that he affords to the elect an irresistible grace, a faith that they cannot lose, which takes away the freedom of will, and necessitates all their actions to virtue. The Calvinists believe that God foreknew a determinate number, in whom he would manifest his glory; and that having thus foreknown them, he predestinated them to be holy, in order to which he gives them an irresistible grace, which makes it impossible for them to be otherwise.

CALYCANTHUS, in botany, a genus of the polygynia order, in the icosandria class of plants, and in the natural method ranked among the plantæ dubii ordinis. The calyx is monophyllous, pitcher form, squarrose, with small coloured leaves, the corolla consisting of the leaves on the calyx; the styles are numerous, each with a glandular stigma; the seeds are many, each with a train, within a succulent calyx. There are two species, *viz.*

1. Calycanthus floridus, or Carolina allspice tree, a native of Carolina. It seldom grows, at least with us, to more than five feet high. It divides into many branches irregularly near the ground. It is of a brown colour; and when bruised emits a most agreeable odour. The leaves that garnish this delightful aromatic are of an oval figure. At the end of these stand the flowers, of a kind of chocolate purple colour. The propagation of this shrub is not very difficult; though more than common care must be taken, after small plants are obtained, to preserve them till they are of a size to be ventured abroad. The last year's shoots, if laid in the ground, the bark being a little bruised, will strike root within a year, particularly if the layers are shaded, and watered in summer.

2. C. præcox is not yet inured to our climate.

CALYPTRA. Most of the mosses have calyptræ. See Botany.

CALYPTRANTHES, a genus of the icosandria monogynia class and order. The essential character is, calyx superior, truncate, covered with a veil shaped rib; corolla none; berry one celled, one to four seeded.

There are six species, trees and shrubs, of the West Indies.

CALYX, among botanists, a general term expressing the cup of a flower, or that part of a plant which surrounds and supports the other parts of the flower. See Botany.

CAMÆA, in natural history, a genus of the semipellucid gems, approaching to the onyx structure, being composed of zones, and formed on a crystaline basis; but having the zones very broad and thick, and laid alternately on one another, with no common matter between; usually less transparent, and more debased with earth, than the onyxes.

1. One species of the camæa is the dull looking onyx, with broad black and white zones; and is the camæa of the moderns, and the Arabian onyx; this species is found in Egypt, Arabia, Persia, and the East Indies. 2. Another species of the camæa is the dull, broad zoned, green and white camæa, or the jaspi cameo of the Italians: it is found in the East Indies, and in some parts of America. 3. The third is the hard camæa, with broad white and chesnut coloured veins. 4. The hard camæa, with bluish, white, and flesh coloured broad veins, being the sardonyx of Pliny's time, only brought from the East Indies.

CAMALDULIANS, a religious order founded by St. Romuald, in a little plain, on the mount Apennine, called Camaldali, situated in the state of Florence.

The manner of life first enjoined this order was, that they dwelt in separate cells, and met together only at the time of prayer: some of them, during the two Lents of the year, observed an inviolable silence; and others for the space of a hundred days. On Sundays and Thursdays they fed on herbs, and the rest of the week only on bread and water. These constitutions were, however, a little moderated some time afterward. This hermitage is now accounted very opulent.

CAMAX, in botany, a genus of the class and order pentandria monogynia. The essential character is, corolla wheel shaped; filaments inserted between the segments of the corolla; berry four celled, many seeded.

There is one species, a native of Guiana.

CAMBER BEAM, among builders, a piece of timber in an edifice, cut archwise, or with an obtuse angle in the middle, commonly used in platforms, as church leads, and on other occasions where long and strong beams are required.

CAMBLET, or *camlet*, a plain stuff, composed of a warp and woof, which is manufactured on a loom, with two treadles, as linens are. There are camblets of several sorts: some of goat's hair, both in the warp and woof; others, in which the warp is of hair, and the woof half hair and half silk; others again, in which both the warp and the woof are of wool; and lastly, some of which the warp is of wool and the woof of thread; some are striped, some waved or watered, and some figured.

CAMBOGIA, in botany, a genus of the monogynia order in the polyandria class of plants, and in the natural method ranking under the 39th order, tricoccæ. The corolla is tetrapetalous; the calyx tetraphyllous; and the fruit is a pome with eight cells, and solitary seeds. There is but one species, *viz.*

Cambogia gutta, a native of India. It yields the gum resin known by the name of gamboge.

CAMBRICS, a species of very fine white linen, made of flax at Cambray.

Of so much repute are French cambrics, that for many years more than 200,000*l.* per annum was expended in them by the inhabitants of this country. Parliament interfered, and the wearing and selling of foreign cambrics are prohibited under heavy penalties. The cambrics now allowed in this country are chiefly manufactured in Scotland and Ireland.

CAMELLIA, in botany, a genus of the monadelphia polyandria class, and in the natural method ranking under the 37th order, columniferæ. The calyx is imbricated and polyphyllous, with the interior leaves larger than the exterior. There are three species, natives of China and Japan. Thunberg, in his Flora Japonica, describes it as growing every where in the groves and gardens of Japan; where it becomes a prodigiously large and tall tree, highly esteemed by the natives for the elegance of its large and very variable blossoms, and its evergreen leaves. It is there found with single and double flowers, white, red, and purple, produced from April to October. Representations of this flower are frequently met with in Chinese paintings. With us the camellia is generally treated as a greenhouse plant, and propagated by layers. At some future time it may, perhaps, not be uncommon to treat it as a laurustinus or magnolia: the high price at which it has hitherto been sold, has probably prevented its being hazarded in this way. The blossoms are of a firm texture, but apt to fall off long before they have lost their brilliancy.

CAMELOPARDALIS, a genus of the order of pecora. The generic character is; horns permanent, bony, covered with a bristly skin; front teeth in the lower jaw eight; the exterior one on each side deeply bilobate. If height alone constituted precedency among quadrupeds, the giraffe, or camelopardalis, see Plate XXV. Nat. Hist. fig. 77. would undoubtedly claim the first rank; measuring, when full grown, near seventeen feet from the top of the head to the fore feet. The female, however, is lower than the male, and the measure abovementioned must be understood to relate to the animal when arrived at the utmost limits of its tallest growth, the generality of those described by travellers not exceeding fifteen or sixteen feet. Notwithstanding the unusual proportions of this animal, its general form is in the highest degree elegant and picturesque: the head being small, the aspect mild, the neck extremely long and tapering; the fore parts much higher than the hinder; and the disposition of the colours singular and pleasing. At first view, the fore legs seem nearly twice the length of the hind; but this difference, on accurate examination, appears to result chiefly from the extraordinary height of the shoulders, compared with that of the thighs.

The horns of the camelopardalis differ in texture from those of all other horned quadrupeds, forming a part of the skull, and consisting of a porous bony substance, covered externally with short coarse bristly hair: they terminate abruptly, in a flattish or slightly convex head, but little wider than the other part of the horn, and edged with

stiff bristles all round the outline. On the middle of the forehead rises a considerable protuberance, owing to an elevation or bony rising on that part of the skull. From the head to the middle of the back runs a short stiffish mane. The tail is of moderate length, and of a cylindrical form, gradually tapering toward the end, and terminating in a tuft of long hair. The hoofs are moderately large and black. The fore part of the body is very thick and muscular, and the hind part thin and meagre. The ground colour of the animal is whitish, variegated on all parts with numerous, moderately large, and somewhat squarish spots; which in the male are brown, and in the female ferruginous. In the younger animals they are sometimes of a bright reddish yellow. These marks or spots are of a somewhat less regular shape on the sides than on the neck and shoulders.

The camelopardalis is a native of Ethiopia, and some other parts of Africa; where it is chiefly found in forests, living on herbage of various kinds, but principally on the foliage of trees, and particularly on some species of mimosa. When grazing on the surface of the ground, it is observed to spread its fore legs very considerably, in order to enable it to reach the ground with greater facility. It is an animal of a mild and harmless disposition, and when attacked, endeavours merely to save itself by flight; running with great swiftness, though in a somewhat peculiar and awkward style, on account of the length of its neck, and breadth of its fore parts compared with the hind.

The male and female camelopardalis resemble each other when young: but as the animal advances in age, the spots on the male become dark brown, while those of the female continue of a ferruginous cast. In both, however, some occasional differences of shade take place; and the female, when very old, is said to acquire the dusky shades of the male. The female has also a less conspicuous tubercle on the forehead, and has four teats, as in a cow.

These animals are sometimes seen in small groups, to the number of six or seven together, and when disturbed run off with great celerity. When seen in front, at some little distance, the animal might be mistaken for a decayed tree, and thus be easily passed by without particular notice.

Camelopardalis, in astronomy, a new constellation of the northern hemisphere, formed by Hevelius, consisting of 32 stars, first observed by him, situated between Cepheus, Cassiopeia, Perseus, the two Bears, and Draco. It contains about 58 stars in the British catalogue.

CAMELUS, *camel*, a genus of quadrupeds of the order of pecora. The generic character is, horns none; front teeth in the lower jaw six, somewhat thin and broad; canine teeth distant, in the upper jaw three, in the lower two: upper lip divided. There are seven species.

1. C. dromedarius, Arabian camel, or dromedary, is found in the warmer parts of Asia, and in the upper regions of Africa. In Asia it is said not to be found further north than Persia, and in Africa not further south than Ethiopia. It is common in most parts of India. See Plate XXV. Nat. Hist. fig. 71.

The general height of the Arabian camel, measured from the top of the dorsal bunch to the ground, is about six feet and a half; but from the top of the head, when the animal elevates it, not much less than nine feet: the head, however, is generally so carried as to be nearly on a level with the bunch, or rather below it, the animal bending the neck extremely in its general posture: the head is small, the neck very long, the body of a long and meagre shape, the legs rather slender, and the tail, which is slightly tufted at the end, reaches to the joints of the hind legs; the feet are very large, and are hoofed in a peculiar style, being divided above into two lobes not reaching through the whole length of the foot, and the extremity of each lobe is guarded by a small hoof: the under part of the foot is covered with an extremely strong, tough, and pliable skin, which, by yielding in all directions, enables the animal to travel with peculiar ease and security over dry, stony, and sandy regions. On each leg are six callosities. On the lower part of the breast is also a large callus or tough tubercle, which is gradually increased by the constant habit which the animal has of resting upon it in lying down. It is distinguished from the succeeding species by having a single large bunch on the back.

The general colour of the camel is an uniform dusky brown, more or less tinged with ferruginous. Its hair is fine and soft, and serves for the basis of several kinds of stuffs.

There are several varieties of this animal, differing in size, strength, &c. analogous to the different breeds of horses.

2. C. Bactrianus, Bactrian camel, in its general appearance so much resembles the Arabian, that it might rather seem a permanent variety of that animal than a distinct species; differing only in being somewhat larger, and in having two bunches on the back instead of one. It is said to be found wild in the northern parts of India, and in the deserts bordering on China, and is more esteemed for swiftness than the Arabian camel. See Plate XXV. Nat. Hist. fig. 73.

In Arabia it is kept chiefly for the use of the great, being not a native of that country, but imported from India, &c. Of this animal, as well as of the Arabian camel, there are several races or varieties, differing, like those of horses, in strength, size, swiftness, and elegance of form. A breed of peculiar swiftness is said to be reared in China, and to be distinguished by the expressive title of *fong kyo fo*, or camels with feet of wind. A white variety occurs in some parts of Siberia; and lastly, a hybrid or mixed breed is said to be occasionally obtained between the Bactrian and the Arabian camel.

3. Camelus glama. This animal, described by some of the old naturalists under the name of ovis Peruviana, or Peruvian sheep, is a native of South America, and is particularly plentiful in Peru, where it inhabits, in a wild state, the highest and coldest parts of mountains, feeding in numerous herds, and flying with great rapidity on the sight of mankind. It was, however, completely subdued and domesticated by the ancient Peruvians, being the only beast of burden known to that people, to whom it answered the same purposes as the camel and dromedary in the eastern regions of the old continent. The general size of the glama is nearly that of a stag; measuring about four feet and a half in height to the top of the shoulders, and about six feet in length from nose to tail. The neck is a great length; the head small; the back slightly elevated, and the whole animal bears some resemblance to a camel on a smaller scale. Its general colour is a light

ferruginous brown, paler or whitish on the under parts; and sometimes it is said to be varied or patched with darker and lighter shades on different parts, and to have a black stripe running down the back to the beginning of the tail. See Plate XXV. Nat. Hist. fig. 75.

The voice of the glama resembles the shrill neighing of a horse. When angry or attacked, it strikes with its feet, and endeavours to bite. The glama is said to be able to carry a burden of about a hundred and fifty pounds weight, and to travel at the rate of three German miles a day for three or four days together. When resting, it leans on its breast in the manner of the camel, which it also resembles in the faculty of abstaining long from drink, sometimes four or five days; and, like that animal, may be supported by very coarse and trifling food. Its flesh is said to resemble mutton in flavour.

4. Camelus vicuna. The vicuna bears a general resemblance to the glama; but is of a lighter and more delicate aspect, and of smaller size; the head is smaller and shorter in proportion; the eyes remarkably large and full; the ears somewhat sharper, and the limbs more slender. The hair of this animal is of a very soft, wavy, and woolly nature; that on the breast is nearly three inches long, on the other parts not more than one inch; the end of the tail is furnished, like the breast, with long woolly hair. See Plate XXV. Nat. Hist. fig. 76.

The vicuna affords the finest wool of any, and it is wrought into cloths of most exquisite silky softness and beauty, which are said to be too warm for common wear, unless made peculiarly thin.

The vicuna, as well as the paco or next species, is sometimes taken by the Peruvians by the simple artifice of tying cords, with bits of wool or cloth fixed to them at certain distances, at three or four feet from the ground, across the narrow passes of the mountains; and when the animals have been hunted or driven that way, they are so terrified by the fluttering of the rags, that, instead of attempting to pass, they huddle together in heaps, and thus afford their pursuers an opportunity of killing with their slings as many as they please.

5. Camelus paco. This species is said to be entirely confined to Peru, where the natives keep vast flocks of them for the sake of the wool, of which they prepare cloth of silky lustre and softness. Like the vicuna, it is found in mountainous districts in large herds, but is never observed to associate with those animals. It is of a more robust make than the vicuna, and is covered with very long wool; which is, in the wild animal, of a dull purple colour, resembling that of dried rose leaves, but in the domesticated kind is often varied with black, white, and rufous; the belly is white. Like the two preceding species, it has sometimes been named the Peruvian sheep. Those concretions, known by the name of bezoars, are often found in the stomach of this as well as of other species.

6. Camelus huanacus, or the guanaco, is a native of Peru, and is found in similar situations with the glama and the paco. It is the largest of all the Peruvian animals of this kind, and is said sometimes to grow to the size of a horse. Its back is pretty much arched; and it is covered not with wool like the other smaller species, but with long smooth hair; the head is round, the nose somewhat pointed, the ears straight like those of a horse, and the tail short and turning upward. It appears to be more nearly allied to the glama than to any other species, but is said never to associate with that animal. Its general colour is tawny above and white below.

7. Camelus arcuanus. This species, which inhabits Peru and Chili, is described as measuring about six feet in length, and about four in height. It is covered with woolly hair, and in its general appearance is not unlike a ram. The ears are flaccid or pendulous, the neck and legs long; the tail like that of a sheep, but shorter in proportion: the wool is very soft, and the colour of the animal is said to vary in different individuals, being either brown, black, ash coloured, or white. This animal was employed by the ancient inhabitants of Chili as a beast of burden, as well as in ploughing. Its wool was also used in the manufacture of a fine silky cloth or stuff; but this is now said to have given place to the introduction of European wool, as being stronger and more serviceable.

CAMEO. See Camæa.

CAMERA OBSCURA. See Optics.

CAMERARIA, in botany, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 30th order, contortæ. There are two horizontal follicles at the base of the seed case. The seeds are inserted into a proper membrane. There are two species, *viz.*

1. Cameraria angustifolia, has an irregular shrubby stalk, which rises about eight feet. The flowers are produced scatteringly at the end of the branches, which are shaped like those of the latifolia, but smaller. It is a native of Jamaica.

2. Cameraria latifolia, a native of the island of Cuba. It rises with a shrubby stalk to 10 or 12 feet, dividing into several branches, with roundish pointed leaves placed opposite. The flowers are produced at the end of the branches in loose clusters, which have long tubes enlarging gradually upward; and at the top are cut into five segments, broad at their base, but ending in sharp points: the flower is of a yellowish white colour.

CAMERLINGO, according to Ducange, signified formerly the pope's or emperor's treasurer: at present camerlingo is no where used but at Rome, where it denotes the cardinal who governs the ecclesiastical state, and administers justice.

CAMERONIANS, a party of presbyterians, which sprung up in Scotland in the reign of king Charles II. They affirmed that the king had forfeited his right to the crown, by breaking the solemn league and covenant, which were the terms on which he received it. They pretended both to dethrone and excommunicate him, and broke out into open rebellion. Upon the Revolution they were reconciled to the kirk, and their preachers submitted to the general assembly of the church of Scotland in 1690.

CAMP, in military affairs, is the whole extent of ground, in general, occupied by an army pitching its tents when in the field, and upon which all its baggage and apparatus are lodged. It is marked out by the quartermaster general, who allots every regiment its ground. The extent of the front of a regiment of infantry is 200 yards, including the two battalion guns, and depth 320, when the regiment contains nine companies, each of 100 private men, and the companies' tents in two rows; but when the

companies' tents stand in one row, and but 70 private men to each row, the front is then but 155 yards. A squadron of horse has 120 yards in front, and 100 for an interval between each regiment.

The nature of the ground must also be consulted, both for defence against the enemy, and for supplies to the army. It should have a communication with the army's garrisons; and have plenty of water, forage, fuel; and either rivers, marshes, hills, or woods, to cover it. An army always encamps fronting the enemy, and generally in two parallel lines, besides a corps de reserve, about 500 yards distant from each other; the horse and dragoons on the wings, and the foot in the centre. Each regiment posts a subaltern's guard at 80 yards from the colours to the officer's tent, called the quarter guard, besides a corporal's guard in the rear; and each regiment of horse or dragoons, a small guard on foot, called the standard guard, at the same distance. The grand guard of the army consists of horse, and is posted about a mile distant toward the enemy.

In a siege, the camp is placed all along the line of circumvallation, or rather in the rear of the approaches, out of cannon shot: the army faces the circumvallation, if there is any; that is, the soldiers have the town in their rear. One thing very essential in the establishing a camp, and which should be particularly attended to if the enemy is near, is, that there should not only be a commodious spot of ground at the head of the camp where the army, in case of surprise, may in a moment be under arms, and in condition to repulse the enemy; but also a convenient field of battle at a small distance, and of a sufficient extent for them to form advantageously, and to move with facility.

The arrangement of the tents in camp, is nearly the same all over Europe; which is, to dispose them in such a manner, that the troops may form with safety and expedition. To answer this end, the troops are encamped in the same order as that in which they are to engage, which is by battalions and squadrons; hence, the post of each battalion and squadron in the line of battle, must necessarily be at the head of its own encampment. Gustavus Adolphus, king of Sweden, was the first who formed encampments according to the order of battle. By this disposition, the extent of the camp from right to left, of each battalion and squadron, will be equal to the front of each in line of battle; and consequently, the extent from right to left of the whole camp, should be equal to the front of the whole army when drawn up in line of battle, with the same intervals between the several encampments of the battalions and squadrons, as are in the line. There is no fixed rule for the intervals. The most general method is, an interval of 60 feet between each battalion, and of 36 feet between each squadron.

Hence it follows, 1st, that the front line of the camp must be in a direction to face the enemy; 2dly, that at the head of the encampment of each battalion and squadron, there must be a clear space of ground, on which they may form in line of battle; and, 3dly, that when the space taken up by the army is embarrassed with woods, ditches, and other obstructions, a communication must be opened for the troops to move with ease to the assistance of each other.

The tents for the cavalry, as well as for the infantry, are placed in rows perpendicular to the principal front of the camp; and their number is conformable to the number of troops. The horses of each troop are placed in a line parallel to the tents, with their heads toward them. The number of tents in each row, is regulated by the strength of the troops, and the number of troopers allotted to each tent is 5; it follows, that a troop of 30 men will require six tents, a troop of 60 men 12 tents, and a troop of 100 men 20 tents. The tents of the cavalry are of the same form as those of the infantry; but more spacious, the better to contain the fire arms, accoutrements, saddles, bridles, boots, &c.

CAMPAIGN, in the art of war, denotes the space of time that an army keeps the field, or is encamped, in opposition to quarters.

CAMPANIFORM, or *campanulated*, an appellation given to flowers resembling a bell; a characteristic whereon Tournefort establishes one of his classes of plants. See BOTANY.

CAMPANINI, a name given to a marble of Italy, dug out of the mountains of Carrara; because, when it is worked, it resounds like a bell.

CAMPANULA, the *bell flower*, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 29th order, campanaceæ. The corolla is campanulated, with its fundus closed up by the valves that support the stamina; the stigma is trifid; the capsule inferior, or below the receptacle of the flower, opening and emitting the seeds by lateral pores. Of this genus there are no fewer than 78 species, but the following are the most worthy of attention:

1. Campanula canariensis, with an orach leaf and tuberous root, is a native of the Canary islands. It has a thick fleshy root of an irregular form; the leaves are of a sea green, and when they first come out are covered slightly with an ash coloured pounce; the flowers are the perfect bell shape, and hang downward; they are of a flame colour, marked with stripes of a brownish red.

2. Campanula decurrens, the peach leaved bell flower, is a native of the northern parts of Europe: of this there are some with white, and some with blue flowers, and some with double flowers of both colours.

3. Campanula hybrida, or Venus's looking-glass, seldom rises more than six inches; the branches are produced, which are terminated by flowers very like the speculum. This was formerly cultivated in the gardens; but since the speculum has been introduced, it has almost supplanted this.

4. Campanula latifolia, or greatest bell flower, has a perennial root, and several strong, round, single stalks. The flowers come out singly upon short footstalks; their colours are blue, purple, and white.

5. Campanula medium, the Canterbury bell flower, is a biennial plant, which perishes soon after it has ripened its seeds. It is well known.

6. Campanula pyramidalis, has thick tuberous roots; it sends out strong, smooth, upright stalks, which rise to the height of 4 feet. The flowers are produced from the sides of the stalks, and are regularly set on for more than half their length, forming a sort of pyramid. The most common colour of the flowers is blue, though some are white.

7. Campanula rapunculus, the rampion, has roundish fleshy roots, which are eatable, and much cultivated in

France for sallads; some years past, it was cultivated in the English gardens for the same purpose, but is now generally neglected.

8. Campanula speculum, with yellow eyebright leaves, is an annual plant with slender stalks rising a foot; from the wings of the leaves come out the flowers sitting close to the stalks, which are of a beautiful purple inclining to a violet colour.

9. Campanula trachelium, with nettle leaves, has a perennial root, and stiff hairy stalks: the flowers are blue and white; some have double flowers.

CAMPHOR. The laurus camphoratus is a tree which grows in China, Japan, and several parts of India.

The wood and roots being boiled with water, the camphor rises with the steam, and is condensed, in straw placed in the capital, &c. of the still, in small glandular crystals, together with another sort, apparently scraped from the cavities of the wood, and mixed with sand, ashes, &c. and purified by a second sublimation by the English and Dutch chymists. This operation is performed in shallow matrasses, technically termed *bumbelois*, on a sand heat. The camphor melts at 360 degrees, boils and sublimes solid and transparent. Its vapour is so heavy, that very little escapes, though the mouth is open. It is volatile at all temperatures, and exhales in toto when exposed. It is crystalizable either by cooling when melted, by sublimation at a low heat, or from its solvents at an angle of 60 degrees: hence it forms figures like those of ice.

Its solvents are alcohol, acids, especially the mineral, essential and fat oils. From all solvents but the two latter it is separable, unchanged by water. Its specific gravity is 0.9887. Hence it just floats on water, but sinks readily in spirits. Small thin cuttings thrown on clean warm water are affected with a strong rotatory motion till an oily film has overspread the surface, when it ceases.

It is transparent as glass when pure and newly sublimed, and is highly refractive. It catches flame very readily, and emits a great deal of flame as it burns, but it leaves no residuum. It is so inflammable that it continues to burn even on the surface of water. When camphor is set on fire in a large glass globe filled with oxygen gas, and containing a little water, it burns with a very bright flame, and produces a great deal of heat. The inner surface of the glass is soon covered with a black powder, which has all the properties of charcoal, a quantity of carbonic acid gas is evolved, the water in the globe acquires a strong smell, and is impregnated with carbonic acid and camphoric acid.

From an useful analysis, M. Bouillon Lagrange concludes that camphor is composed of volatile oil and charcoal or carbon combined. From his experiments we learn that the ultimate ingredients of camphor are carbon and hydrogen, and that the proportion of carbon is much greater than in oils.

Camphoric acid is the result of the change produced on camphor by distilling nitric acid several times from it. It crystalizes in parallelopipeds, is efflorescent, soluble in water, and volatile in a strong heat.

CAMPHOROSMA, in botany, stinking ground pine; a genus of the tetrandria order, in the monogynia class of plants, ranking in the natural method under the 12th order, holeraceæ. The calyx is pitcher shaped and indented; there is no corolla; and the capsule contains a single seed. It is reputed cephalic and nervine; though little used in modern practice. It takes the name from its smell, which bears some resemblance to that of camphor. There are five species. Of these the principal is,

Camphorosma monspeliensis, which grows by the road side in Languedoc, and especially about Montpelier. It has been produced as a specific for the dropsy, and asthma.

CANAL, a kind of artificial river, made for the convenience of water carriage.

The Dutch, or if we can believe the relations of travellers, the Chinese, who inhabit a country vastly more extensive than that of the Dutch, have shown the great advantages resulting from canals to a trading people.

There are several large canals in France; that of Briere, begun under Henry IV. and finished under Lewis XIII. establishes a communication between the Loire and the Seine by the Loing. There are forty-two sluices upon it. But the greatest and most wonderful work of that kind, and at the same time one of the most useful, is the junction of the two seas, by the canal of Languedoc, proposed under Francis I. but not finished till the time of Lewis XIV.

The operations necessary for making artificial navigations or canals, depend on the situation of the ground, the connection with rivers, and the ease with which water can be obtained. When the ground is naturally level, and unconnected with rivers, the execution is easy, and the navigation is not liable to be disturbed with floods: but when the ground rises and falls, and cannot be reduced to a level, artificial methods of raising and lowering vessels must be employed. Temporary sluices are sometimes used for raising boats over falls or shoals in rivers by a very simple operation. Two pillars of masonry work with grooves, are fixed, one on each bank of the river, at some distance below the shoal. The boat having passed these posts, planks are let down across the river by pulleys into the grooves, by which the water is dammed up to a proper height for allowing the boat to pass up the river over the shoal.

The Dutch frequently make use of inclined planes or rolling bridges upon dry land, along which their vessels are drawn from the river below into the river above; this was the method employed by the ancients, and is still used by the Chinese, who are said to be ignorant of the nature and utility of locks. These rolling bridges consist of a number of cylindrical rollers which turn easily on pivots; and a mill is commonly built near at hand, so that the same machinery may serve a double purpose of working the mill and drawing up vessels.

Before a canal is undertaken, the following circumstances require consideration.

1st. *Places to be benefited in point of trade.* Trade being the grand source from which adventurers in canal schemes expect to derive their great profits, such towns, places, &c. must be included in the line of a canal, to which the safe, expeditious, and easy conveyance of merchandise, and consequent enlargement of commerce, will be of moment. These can be fixed upon only by an accurate survey and knowledge of the country through which the canal is intended to pass.

2dly. *The supply of water*, &c. It is almost needless to mention the absolute necessity of a supply of water for a canal, which must be in requisite quantities in the summit, or reservoirs, which may be supplied by the neighbouring springs; or if these fail, water must be thrown up by engines from a lower level.

Reservoirs are large bodies of water collected together for the use of such parts of the canal as are likely to be deficient; into which it is let by sluices, when and where wanted.

The quantity of water requisite for the use of a canal depends in a great measure upon the quantity of trade carried on. A lockful of water must be lost every time a boat passes through, which, in a lock whose length in the chamber is seventy-five feet, breadth seven feet, and lift six feet, will be 125 cubic yards of water; which quantity, multiplied by the number of boats likely to pass through the summit lock, will give an idea of the waste of water. Allowance also must be made for exhalation and accidents.

The most eligible level is certainly that which has the least fall and the fewest obstructions, and is best adapted to the face of the country.

The soil most favourable for a canal is clay; the most unfavourable, sand. As soils approach more or less to the quality of clay or sand, in such proportion are they to be preferred for holding water.

Of the expense of execution little can be said, as it entirely depends on the extent, the several works, &c. which can be accurately known only by an actual survey and estimate, the total of which will of course be considered previous to undertaking works of such magnitude. It may be proper to observe generally, that many locks, bridges, or aqueducts, much tunneling, unfavourable soil, &c. will of necessity incur great expenses.

Lastly. *The mode of execution.* The foregoing particulars having been attended to, it becomes necessary to enumerate the several works, useful and necessary, in the execution of a canal.

For the passing and repassing of boats, there are various expedients, some of which have been noticed; but experience confirms the use of locks, when it becomes necessary, by artificial means, to raise or let down boats from one level to another.

A lock is a large basin, or, more properly, a long square cistern, placed lengthwise in a river or canal, enclosed by upper and lower gates. The lock should be lined with walls of strong masonry on each side, and at the bottom; or if wood, stout oak piles should be used, shod with iron, and lined with two inch and a half or three inch oak plank, with a floor of the same materials, laid on oak sleepers, dovetailed and spiked into the upright piles.

The use, or locking down, is thus managed: the lock being full to the level of the upper water, the gates are then shut, including the boat to be lowered. The water in the lock is drawn off; in part first, by means of the paddles in the gates, and completely by the gates being opened; when the boat, being upon a level with the lower water, is able to proceed upon its passage. For ascending, or locking up, the boat being in the lock, the lower gates are shut: the lock is then filled with the upper water, first by the sluices, and finally by the gates being opened: thus the vessel is on a level with the upper water, and may immediately proceed.

In the first figure; see Plate XXIV. we have a perspective view of part of a canal, with a vessel within a lock, on the upper level of the water. The second figure shows a section of an open lock, with a vessel about to enter. A, B, in the former figure, are flood gates; each of which consists of two leaves resting upon one another, so as to form an obtuse angle, in order to resist the pressure of the water. A, when shut, prevents the water of the superior canal fron falling into the lock, and B sustains the water in the lock. D, in the second figure, is the subterraneous passage by which the water passes from the upper level into the lock when the sluice *d* is opened; and C is the passage by which the water in the lock is let out when the sluice *c* is raised; and thus the vessel in the lock is brought on a level with the lower part of the canal.

CANARINA, in botany, a genus of the order monogynia, belonging to the hexandria class of plants. The calyx is six leaved; corolla six cleft, bill form. There are 2 species.

CANARIUM, in botany, a genus of the dioecia order, in the pentandria class of plants. Its characters are, that it has male and female flowers; that, in both, the calyx has two leaves, and the corolla consists of three petals: the fruit is a drupa with a three cornered nut. There is but one species.

CANCER, in astronomy, one of the 12 signs, represented on the globe in the form of a crab, and thus marked (♋) in books. It is the fourth constellation in the starry zodiac. The reason generally assigned for its name as well as figure, is a supposed resemblance which the sun's motion in this sign bears to the crab's. As the latter is said to walk backward, so the former, in this part of his course, begins to go backward, or recede from us. By others, the disposition of stars in this sign is supposed to have given the first hint to the representation of a crab. It gives name to a quadrant of the ecliptic, *viz.*

CANCER, tropic of, in astronomy, a lesser circle of the sphere parallel to the equator, and passing through the beginning of the sign Cancer.

CANCER, in medicine, a roundish, unequal, hard, and livid tumour, generally seated in the glandulous part of the body, supposed to be so called because it appears at length with turgid veins shooting out from it, so as to resemble, as it is thought, the figure of a crab fish; or, others say, because, like that fish, where it has once got, it is scarcely possible to drive it away. See MEDICINE.

CANCER, in zoology, a genus of insects belonging to the order of insecta aptera. The generic characters are these: they have eight legs, (seldom ten or six,) besides two large claws which answer the purpose of hands. They have two eyes at a considerable distance from each other, and for the most part they are supported by pedunculi or footstalks: the eyes are elongated and moveable. They have two clawed palpi, and the tail is jointed. There are eighty-seven species of the cancer, distinguished principally by the length of their tails, and the margin of their breasts. The following are the most remarkable:

1. Cancer astacus, or the craw fish, with a projecting snout slightly serrated on the sides; a smooth thorax; back smooth, with two small spines on each side; claws large, beset with small tubercles; two first pair of legs clawed, the two next subulated; tail consisting of five

joints; the caudal fins rounded. It inhabits many of the rivers in England, lodging in holes which they form in the clayey banks.

2. Cancer atomos, atom lobster, with a slender body; filiform antennæ; three pair of legs near the head; beyond are three pair of legs, and a slender tail between the last pair. It is very minute, and the help of the microscope is often necessary for its inspection.

3. Cancer crangon, the shrimp, with long slender feelers, and between them two projecting laminæ; claws with a single, hooked, moveable fang. It inhabits the shores of Britain in vast quantities.

4. Cancer stagnalis, is found generally in small shallow pools of rain water, and is very transparent. The head of the male is armed with fangs; the tail of the female is furnished with a bag of eggs at the base. See Plate XXV. Nat. Hist. fig. 78.

5. Cancer diogenes, soldier crab, or hermit crab, with rough claws; the left claw is the longest. This species is parasitic, and inhabits the empty cavities of turbinated shells, changing its habitation according to its increase of growth from the small nerite to the large whelk. They crawl very fast with the shell on their back, and at the approach of danger draw themselves within the shell, and thrusting out the larger claw, will pinch very hard whatever molests them. When it wants to change its shell, it travels along that line of pebbles and shells which is formed by the extremest wave; still, however, dragging its old incommodious habitation at its tail, unwilling to part with one shell, even though a troublesome appendage, till it can find another more convenient. It is seen stopping at one shell, turning it, and passing it by; going on to another, contemplating that for a while, and then slipping its tail from its old habitation to try on the new: if this also is found to be inconvenient, it quickly returns to its old shell again. It is not till after many trials, and many combats also, that the soldier is completely equipped; for there is often a contest between two of them for some well looking favourite shell for which they are rivals. When this animal is taken, it sends forth a feeble cry, endeavouring to seize the enemy with its nippers; which if it fastens upon, it will sooner die than quit the grasp. See Plate XXVIII. Nat. Hist. fig. 110.

6. The strigosus, or plated lobster, with a pyramidal spiny snout; thorax elegantly plated, each plate marked near its junction with short striæ; only three legs spiny on their sides; tail broad. The largest of this species is about six inches long. It inhabits the coasts of Anglesea. See Plate XXVIII. Nat. Hist. fig. 109.

7. Cancer gammarus, the common lobster, inhabits the rocky shores of our island, but chiefly where there is a depth of water. In Llyn in Caernarvonshire a certain small lobster, nothing different except in size, burrows in the sand. Lobsters fear thunder, and are apt to cast their claws on a great clap: it is said that they will do the same on the firing of a great gun; and that, when men of war meet a lobster boat, a jocular threat is used, that if the master does not sell them good lobsters, they will salute him. This species inhabits the clearest water, at the foot of rocks that impend over the sea; which has given opportunity of examining more closely into the natural history of the animal, than of many others who live in an element, that in a great measure limits the inquiries of the most inquisitive. Some lobsters are taken by hand; but the greater quantity in pots, a sort of trap formed of twigs, and baited with garbage. They are formed like a wire mousetrap, so that when the lobster gets in, it cannot return. Lobsters begin to breed in spring, and continue breeding most part of the summer. Dr. Baster says he counted 12,444 eggs under the tail, besides those that remained in the body unprotruded. They deposite those eggs in the sand, where they are soon hatched. Lobsters change their shells annually. They acquire an entire new coat in a few days; but during the time that they remain defenceless, they seek some very lonely place, for fear of being devoured by such of their brethren as are not in the same situation. It is remarkable, that lobsters and crabs renew their claws, when accidentally torn off; and they grow again in a few weeks, though they never attain to the size of the first. They are very voracious animals, and feed on sea weeds, garbage, and all sorts of dead bodies. Though the ova are cast at all seasons, they seem only to come to life in July and August. Great numbers of them may then be found, in the form of tadpoles, swimming about the little pools left by the tides among the rocks, and many also under their proper form from half an inch to four inches in length. In casting their shells, it is hard to conceive how the lobster is able to draw the flesh of their large claws out, leaving the shells entire and attached to the shell of their body, in which state they are constantly found. The fishermen say, the lobster pines before casting, till the flesh of its large claw is no thicker than the quill of a goose, which enables it to draw its parts through the joints and narrow passage near the trunk. The new shell is quite membranaceous at first, but hardens by degrees. Lobsters only grow in size while their shells are in their soft state. They are chosen for the table, by their being heavy in proportion to their size; and by the hardness of their shells on their sides, which, when in perfection, will not yield to moderate pressure.

8. Cancer granulatus, or rough shelled crab; these crabs are pretty large, and are commonly taken from the bottom of the sea in shallow water; the legs are small in proportion to the body; the two claws are remarkably large and flat. The whole shell is covered over with innumerable little tubercles like shagreen: the colour is brown, variously stained with purple.

9. Cancer grapsus, or the red mottled crab, has a round body, the legs longer and larger than in other kinds; the claws are red, and the rest of the animal is mottled in a beautiful manner with red and white. These crabs inhabit the rocks hanging over the sea; they are the nimblest of all crabs, and run with surprising agility along the upright side of a rock, and even under the rocks that hang horizontally below the water. This they are often obliged to do for escaping the assaults of rapacious birds that pursue them.

10. Cancer horridus, the horrid crab, with a projecting bifurcated snout, the end diverging; with the claws and legs covered with long and very sharp spines. It is a large species, and inhabits the rocks on the eastern coasts. See Plate XXVIII. Nat. Hist. fig. 111.

11. Cancer locusta, the locust lobster, with four antennæ; two pair of imperfect claws; the first joint ovated; the body consists of fourteen joints. It abounds, in summer,

on the shores, beneath stones and algæ, and leaps about with vast agility.

12. Cancer mænas, the common crab, with three notches on the front; five serrated teeth on each side; claws ovated; next joint toothed; hind feet subulated. It inhabits all our shores; lurks under the algæ, or burrows under the sand.

13. Cancer pagurus, or the black clawed crab, with a crenated thorax; smooth body; smooth claws and black tips; hind feet subulated. It inhabits the rocky coasts; is very delicious meat, and casts its shell between Christmas and Easter.

14. Cancer pisum, the pea crab, with rounded and smooth thorax, entire and blunt; with a tail of the size of the body, which commonly is the bulk of a pea. It inhabits the muscle, and on that account has been deemed poisonous; but the swelling after eating is wholly constitutional.

15. Cancer pulex, the flea lobster, with five pair of legs, and two claws, imperfect; and twelve joints in the body. It is very common in fountains and rivulets; swims very swiftly in an incurvated posture on its back; embraces and protects its young between the legs; does not leap.

16. Cancer ruricola, the land crab, or violet crab, with a smooth entire thorax, and the two last joints of the feet armed with spines. It inhabits the Bahama islands, as well as most lands between the tropics. See Plate XXVIII. Nat. Hist. fig. 112. These animals live not only in a kind of orderly society in the retreats in the mountains, but regularly once a year march down to the sea side in a body of some millions at a time. As they multiply in great numbers, they choose the month of April or May to begin their expedition; and then sally out by thousands from the stumps of hollow trees, from the clefts of rocks, and from the holes which they dig for themselves under the surface of the earth. At that time the whole ground is covered with this band of adventurers; there is no setting down one's foot without treading upon them. The sea is their place of destination, and to that they direct their march with right lined precision. No geometrician could send them to their destined station by a shorter course; they neither turn to the right nor left, whatever obstacles intervene; and even if they meet with a house, they will attempt to scale the walls to keep the unbroken tenor of their way. But though this is the general order of their route, they, upon other occasions, are obliged to conform to the face of the country; and if it is intersected with rivers, they are then seen to wind along the course of the stream. They are often obliged to halt for want of rain, and to go into the most convenient encampment till the weather changes. The main body of the army is composed of females, which never leave the mountains till the rain is set in for some time. The night is their chief time of proceeding; but if it rains by day, they do not fail to profit by the occasion; and they continue to move forward in their slow uniform manner. When the sun shines and is hot upon the surface of the ground, they make an universal halt, and wait till the cool of the evening. When they are terrified, they march back in a confused disorderly manner, holding up their nippers, with which they sometimes tear off a piece of the skin, and then leave the weapon where they inflicted the wound. They even try to intimidate their enemies; for they often clatter their nippers together, as if to threaten those that disturb them. But though they thus strive to be formidable to man, they are much more so to each other; for they are possessed of one most unsocial property, which is, that if any of them by accident is maimed in such a manner as to be incapable of proceeding, the rest fall upon and devour it on the spot, and then pursue their journey. When, after a fatiguing march, and escaping a thousand dangers, (for they are sometimes three months in getting to the shore,) they have arrived at their destined port, they prepare to cast their spawn, which shaking off into the water, they leave accident to bring it to maturity. At this time shoals of hungry fish are at the shore in expectation of this annual supply; the sea at a great distance seems black with them; and about two thirds of the crabs' eggs are immediately devoured by these rapacious invaders. The eggs that escape are hatched under the sand; and soon after, millions at a time of these little crabs are seen quitting the shore, and slowly travelling up to the mountains. This animal, when possessed of its retreats in the mountains, is impregnable: for, only subsisting upon vegetables, it seldom ventures out: and its habitation being in the most inaccessible places, it remains for a great part of the season in perfect security. It is only when impelled by the desire of bringing forth its young, and when compelled to descend into the flat country, that it is taken. At that time, the natives wait for its descent in eager expectation, and destroy thousands; but disregarding their bodies, they only seek for that small spawn which lies on each side of the stomach within the shell, of about the thickness of a man's thumb. They are much more valuable upon their return after they have cast their shell; for, being covered with a skin resembling soft parchment, almost every part except the stomach may be eaten. They are taken in the holes by feeling for them with an instrument; they are sought after by night, when on their journey, by flambeaux. The instant the animal perceives itself to be attacked, it throws itself on its back, and with its claws pinches most terribly whatever it happens to fasten on. But the dexterous crab catcher takes them by the hinder legs in such a manner that the nippers cannot touch him, and thus he throws them into his bag. Sometimes also they are caught when they take refuge in the bottoms of holes in rocks by the sea side, by covering the mouth of the hole to prevent their getting out: and then soon after, the tide coming, enters the hole, and the animal is found, upon its ebbing, drowned in its retreat. These crabs are of various sizes, the largest about six inches wide; they walk sideways like the sea crab, and are shaped like them: some are black, some yellow, some red, and others variegated with red, white, and yellow mixed.

The light coloured are reckoned best; and when full in flesh, are very well tasted.

17. Cancer serratus, or the prawn, with a long serrated snout bending upward; three pair of very long filiform feelers; claws small, furnished with two fangs; five joints to the tail; middle caudal fin subulated, two outmost flat and rounded. It is frequent in several shores among loose stones; sometimes found at sea, and taken on the surface over 30 fathoms depth of water; cinereous when fresh; of a fine red when boiled.

18. Cancer squilla, with a snout like a prawn, but deeper and thinner; the feelers longer in proportion to the bulk; the subcaudal fins rather larger; is, at full growth, not above half the bulk of the former. It inhabits the coasts of Kent; and is sold in London under the name of the white shrimp, as it assumes that colour when boiled.

19. Cancer velutinus, or velvet crab, with the thorax quinquedentated; body covered with short, brown, velvet like pile; claws covered with minute tubercles; small spines round the top of the second joint; hind legs broadly ovated. It inhabits the western coast of Anglesea.

20. Cancer volans, or sand crab, is but of a small size; its colour light brown, or dusky white. It has eight legs, and two claws, one of which is double the size of the other; these claws serve both to defend and feed them. The head has two square holes, which are receptacles for its eyes; out of which it thrusts them, and draws them in again at pleasure. Their abode is only on the sandy shores of Ilathera, and others of the Bahama islands. They run very fast, and retreat from danger into little holes they make in the sand.

CANCROMA, or BOAT BILL, in ornithology, a genus of birds belonging to the order of grallæ; the characters of which are: the bill is broad, with a keel along the middle; the nostrils are small, and lodged in a furrow; the tongue is small; and the toes are divided. There are two species:

1. Cancroma cancrophaga, or the brown boat bill, resembles the cochlearia so much in size, head, crest, and every thing almost, except the colour, that Mr. Latham considers them both as only varieties of the same species. Linnæus however ranks them as distinct. In this species the under parts, instead of ash colour, are of a pale rufous brown; the tail rufous ash; and the upper parts wholly of a cream colour; the bill and legs of a yellow brown. It inhabits Cayenne, Guiana, and Brazil, and chiefly frequents such parts as are near the water: in these places it perches on the trees which hang over the streams, and, like the kingfisher, drops down on the fish which swim beneath. It has been thought to live on crabs likewise, whence the Linnæan name.

2. Cancroma cochlearia, the crested boat bill, as well as the cancrophaga, is of the size of a domestic fowl; the length 22 inches. The bill is four inches long, and of singular form, not unlike a boat with the keel uppermost, or, as some think, like the bowls of two spoons, placed with the hollow parts together; from the hind head springs a long black crest; the feathers which compose it are narrow, and end in a point; the middle ones are six inches in length, the others lessen by degrees; the plumage on the forehead white; the rest of the bird of a pale bluish ash colour; across the lower part of the neck behind is a transverse band of brownish black, which passes forward on each side toward the breast. Its place and manners are the same with those of the cancrophaga.

CANDIDATI MILITES, an order of soldiers among the Romans who served as the emperor's body guards to defend him in battle.

CANDLE, a taper of tallow, wax, or spermaceti, the wick of which is commonly of several threads of cotton, spun and twisted together.

The machine for cutting the cotton is a smooth board made to be fixed on the knees; on the upper surface are the blade of a razor, and a round piece of cane, placed at a certain distance from one another, according to the length of the cotton wanted: the cotton is carried round the cane, and being brought to the razor, is instantly separated from the several balls.

A tallow candle, to be good, must be half sheep's and half bullock's tallow, for hog's tallow makes the candle gutter, and always gives an offensive smell, with a thick black smoke. The wick ought to be pure, sufficiently dry, and properly twisted, otherwise the candle will emit an unconstant vibratory flame, which is both prejudicial to the eyes and insufficient for the distinct illumination of objects.

There are two sorts of tallow candles; the one dipped, the other moulded; the former are the common candles. The tallow is prepared by chopping the fat, and then boiling it for some time in a large copper; and when the tallow is extracted by the process of fire, the remainder is subjected to the operation of a strong iron press, and the cake that is left after the tallow is expressed from it is called greaves: with this dogs are fed, and the greater part of the ducks that supply the London markets. It is also sometimes given to pigs, but certainly without benefiting the flavour of the meat.

When the tallow is in proper order, the workman holds three of the broaches, with the cottons properly spread, between his fingers, and immerses the cotton into the vat containing the tallow: they are then hung on a frame and suffered to cool; and when cold they are dipped again, and so the process is continued till the candles are of the proper size. During the operation the vat is supplied from time to time with fresh tallow, which is kept to the proper heat by means of a gentle fire under it.

The mould in which the moulded candles are cast, consists of a frame of wood, and several hollow metal cylinders, generally made of pewter, of the diameter and length of the candle wanted: at the extremity of these is the neck, which is a little cavity in form of a dome, having a moulding within side, and pierced in the middle, with a hole big enough for the cotton to pass through. The cotton is introduced into the shaft of the mould by a piece of wire being thrust through the aperture of the hook till it comes out of the neck: the other end of the cotton is so fastened as to keep it in a perpendicular situation, and in the middle of the candle; the moulds are then filled with warm tallow, and left to be very cold before they can be drawn out of the pipes.

Besides these, there are other candles made by tallow chandlers, intended to burn during the night without the necessity of snuffing: the wick has been usually made of split rushes; but lately very small cotton wicks have been substituted for the rush: these are lighted much easier, are less liable to go out, and, owing to the smallness of the cotton, they do not require the aid of snuffers.

To make wax candles with the ladle. The wicks being prepared, a dozen of them are tied by the neck, at equal distances, round an iron circle, suspended directly over a large basin of copper tinned, and full of melted wax: a large ladleful of this wax is poured gently on the tops of the wicks one after another, and the operation continued till the candle arrives at its destined bigness, with this

precaution, that the first three ladles be poured on at the top of the wick; the fourth at the height of $\frac{3}{4}$, the fifth at $\frac{1}{2}$, and the sixth at $\frac{1}{4}$, in order to give the candle its pyramidal form. Then the candles are taken down, kept warm, and rolled and smoothed upon a walnut tree table, with a long square instrument of box, smooth at the bottom.

As to the manner of making wax candles by the hand, they begin to soften the wax by working it several times in hot water, contained in a narrow but deep caldron. A piece of the wax is then taken out, and disposed by little and little around the wick, which is hung on a hook in the wall, by the extremity opposite to the neck; so that they begin with the large end, diminishing still as they descend toward the neck. In other respects the method is nearly the same as in the former case. However, it must be observed, that in the former case water is always used to moisten the several instruments, to prevent the wax from sticking; and in the latter, oil of olives, or lard for the hands, &c. The cylindrical wax candles are either made as the former, with a ladle, or drawn. Wax candles, or tapers drawn, are so called because they are actually drawn in the manner of wire, by means of two large rollers of wood turned by a handle, which turning backward and forward several times, pass the wick through melted wax contained in a brass basin, and at the same time through the holes of an instrument like that used for drawing wire, fastened on one side of the basin.

A patent has very lately been obtained for making candles with hollow cylindrical wicks upon the principle of the Argand lamp. See LAMP.

Tallow chandlers and wax chandlers are, by 24 Geo. III. s. 2. c. 41. to take out annual licenses. They shall not use melting houses without making a true entry, on pain of 100*l.* and are to give notice of making candles to the excise officer for the duties, and of the number, &c. or forfeit 50*l.*

CANDLE. Sale or auction by inch of candle, is when a small piece of candle being lighted, the bystanders are allowed to bid for the merchandise that is selling; but the moment the candle is out, the commodity is adjudged to the last bidder.

CANELLA, in botany, a genus of the monogynia order, in the dodecandria class of plants, and in the natural method ranking under the 12th order, holeraceæ. The calyx is three lobed; the petals are five; the antheræ sixteen, growing to an urceolated or bladder shaped nectarium; and the fruit is a trilocular berry, with two seeds. There is but one species, *viz.*

Canella alba. It grows usually about 20 feet high, and 8 or 10 inches in thickness, in most of the Bahama islands. The bark is a warm stomachic.

CANDY, or SUGAR CANDY, a preparation of sugar, made by melting and crystalizing it six or seven times over, to render it hard and transparent. See SUGAR.

CANE, *canna*. See ARUNDO. It is also the name of a long measure, which differs according to the several countries where it is used.

At Naples, the cane is equal to 7 feet 3 inches English measure; the cane of Thoulouse, and the upper Languedoc, is equal to the varre of Arragon, and contains 5 feet $8\frac{3}{5}$ inches; at Montpelier, Provence, Dauphiné, and the lower Languedoc, to 6 English feet $5\frac{1}{3}$ inches.

CANES *venatici*, in astronomy, the greyhounds, two new constellations first established by Hevelius, between the tail of the Great Bear and Bootes's arms, above the Coma Berenices. The first, *viz.* that nearest the Bear's tail, is called asterion; the other chara. They comprehend 23 stars, two only of which were observed by Tycho. In the British catalogue they are 25.

CANINE *teeth*, in anatomy, are two sharp edged teeth in each jaw, one on each side, placed between the incisores and molares.

CANIS, *dog*, in zoology, the name of a comprehensive genus of quadrupeds, of the order of the feræ. The generic character is, cutting teeth in the upper jaw, six; the lateral ones longer, distant; the intermediate ones lobated. In the lower jaw six; the lateral ones lobated. Canine teeth solitary, incurvated. Grinders six or seven, or more than in other genera of this order. There are 24 species.

1st. Canis familiaris, or common dog. The real origin of this species is in a state of uncertainty: wild dogs appear to be found in great troops in Congo, lower Ethiopia, and toward the Cape of Good Hope. They are said to be red haired, with slender bodies and turned up tails, like greyhounds. It is also added that they vary in colour, have upright ears, and are of the general size of a large fox hound. They destroy cattle, and hunt down antelopes and many other animals, and commit great ravages among the sheep of the Hottentots. They are very seldom to be taken, being extremely swift as well as fierce. The young are said to be sometimes obtained, but grow so fierce as to be rendered domestic with great difficulty.

It is not, however, allowed by modern naturalists that these wild dogs constitute the true or real species in a state of nature, but that they are rather the descendants of dogs once domesticated, and which have relapsed into a state resembling that of primitive wildness; and a theory has for some time prevailed, that the wolf is in reality the stock or original from which the dog has proceeded. If, however, the origin of the dog must be traced to some other animal, the jackal seems a more probable origin than the wolf. It is generally believed that the dog was unknown in America on the arrival of Europeans.

That which is supposed by Buffon to approach most nearly to the original animal, is known by the name of the shepherd's dog. This is distinguished by its upright ears, and tail remarkably villose beneath. In the Alpine regions, as well as in some other parts of Europe, this dog is much larger and stronger than in England. Its principal use is as a guard to the flock, which it prevents from straggling, and defends from all attacks.

The dingo, or New Holland dog, approaches in appearance to the largest kind of shepherd's dog. The ears are short and erect; the tail rather bushy; the hair, which is of a reddish dun colour, is long, thick, and straight. This dog is capable of barking, though not so readily as the European dogs: it is extremely fierce, and has the same sort of snarling and howling voice as the larger dogs in general. By some it has been erroneously said neither to bark nor growl. Those which have been brought over to Europe were of a savage and untractable disposition.

The Pomeranian dog is distinguished by upright ears, long hair on the head, and an extremely curved tail, so as to form almost a circle. This dog is generally of a white colour.

The Siberian dog is nearly allied to the preceding, and may be subdivided into several races, differing as to strength and size. The Siberian dogs are principally used in that country and in Kamtschatka for drawing sledges over the frozen snow in winter. When yoking to the sledge, they set up a dismal yell, which ceases on beginning the journey, and then gives place to silent subtlety, and a perpetual endeavour to weary out the patience of the driver by wayward tricks and contrivances.

The Iceland dog seems to differ but slightly from the preceding kind. It has a shortish muzzle, upright ears, with flaccid tips, and is covered with long roughish hair. Its general colour is blackish: the breast, legs, and tip of the tail often white.

The water dog is distinguished by its curly hair, like wool. It is remarkable for its great attachment to the water, swims with great ease, and is used in hunting ducks, and other aquatic birds. Its feet are commonly said to approach more to a webbed form than those of most other dogs.

The great water spaniel is also distinguished in a similar manner by its curled hair, and its propensity to the water. There is a smaller variety of the water dog, called the little barbet, which, in general appearance, extremely resembles the larger.

The Newfoundland dog is of a very large size, and from its strength and docility, is one of those which are best calculated for the security of a house. This animal is remarkably fond of plunging into the water. See Plate XXVI. Nat. Hist. fig. 85.

King Charles's dog is one of the most elegant varieties of the dog, and it is recorded that king Charles the Second hardly ever walked out without being attended by some of this breed. It is in some degree allied to the small water spaniel, and is generally black, with the roof of the mouth of the same colour.

The Maltese dog is also a very small kind of spaniel, generally of a white colour.

The hound admits of some varieties. The old English hound is distinguished by its great size and strength. Its power of smelling is exquisite, and it is said to be able to distinguish the scent an hour after the lighter beagles have given it up. These dogs are said to have been once very common in every part of England, and to have been much larger than at present, the breed having, as it should seem, been gradually suffered to decline.

The bloodhound is a very large dog, taller and more beautifully formed than the old English hound, and superior to most others in speed, strength, and sagacity. The bloodhound was in much esteem with our ancestors for the pursuit of robbers, &c. It was mostly of a reddish or brown colour. "A person of quality," says Mr. Boyle, "to make a trial whether a young bloodhound was well instructed, caused one of his servants to walk to a town four miles off, and then to a market town three miles from thence. The dog, without seeing whom he was to pursue, followed him by the scent to the above mentioned places, notwithstanding the multitude of market people that went along the same way, and of travellers that had occasion to cross it; and when the bloodhound came to the chief market town, he passed through the streets without taking notice of any of the people there, nor did he stop till he had gone to the house where the man he sought rested himself, and found him in an upper room, to the wonder of those that followed him."

The pointer is employed principally in finding partridges and other game. The large pointer, commonly termed the Spanish pointer, is supposed to distinguish itself by a greater degree of docility than the English pointer, but is not able to undergo the fatigues of the field so well.

The Dalmatian, or coach dog, is an animal of great beauty. Its native country seems uncertain. Mr. Pennant, however, informs us that Dalmatia is the country of this elegant dog. It is white, and beautifully marked with numerous black spots. See Plate XXVI. Nat. Hist. fig. 88.

The Irish greyhound is supposed to be the largest of all the dog kind, as well as the most beautiful and majestic in its appearance. It is only to be found in Ireland, and even there is become extremely rare.

The common greyhound is remarkable for the slenderness of its shape, the length of its snout, and the extreme swiftness of its course. The greyhound wants the faculty of quick scent, and follows his prey merely by the eye. The Italian greyhound is a small and beautiful variety of the former. See Plate XXVI. Nat. Hist. fig. 89.

The naked dog is naturally divested of hair, and is supposed to have originated in some very warm climate.

The mastiff is of a very strong and thick form, with a large head, a bold countenance, and large lips hanging down on each side. Dr. Caius, who lived in the reign of Elizabeth, and who described the several varieties of English dogs, tells us that three mastiffs were reckoned a match for a bear, and four for a lion; but from an experiment made in the Tower in the reign of James the First, a lion was found an unequal match to only three. Two of the dogs were disabled by the combat, but the third forced the lion to seek for safety by flight. See Plate XXVI. Nat. Hist. fig. 86.

The bull dog is a kind of mastiff on a smaller scale, with a somewhat flatter snout, and a greater ferocity of aspect. The bull dog is remarkable for the undaunted and savage pertinacity with which it provokes and continues the fight, and when it has fixed its bite, is with extreme difficulty disengaged from its antagonist. The pug dog is a small and innocent resemblance of the former, and is in some countries considered as a kind of lap dog. See Plate XXVI. Nat. Hist. fig. 87.

The terrier is generally an attendant on every pack of hounds, and is very expert in forcing foxes or other game out of their coverts. It is the determined enemy of all the vermin kind; such as weasels, foumarts, badgers, rats, mice, &c.

The turnspit is a breed very much on the decline in England, though still used in some other countries. It is a long bodied, short legged dog, with crooked or bowed knees, and is commonly of a dusky gray, spotted with black. To these we may add the alco, or Peruvian dog, and several mixed breeds from the above.

2d. Canis lupus, or wolf, is distinguished from the dog by his superior size, stronger limbs, more muscular body, and greater breadth of the upper part of the face, while the whole form of it is longer: the tail also, which in the dog is pretty uniformly turned a little toward one side, generally the left, in the wolf has an inward direction; it is rather long and bushy. The wolf is a native of almost all the temperate and cold regions of the globe. It is found in most countries of Europe, but has been totally extirpated from England, as well as from Ireland.

The general colour of the wolf is a pale gray, with a cast of yellowish, but it varies much as to the shades or gradations of colour in different parts of the world.

The wolf is sometimes affected with madness, attended with similar appearances to those exhibited in that state by the dog, and productive of the same symptoms in consequence of its bite: this disease is said to happen to them in the depth of winter, and therefore, as Mr. Pennant observes, can never be attributed to the rage of the dog days. Wolves in the northern parts of the world sometimes, during the spring, get on the ice of the sea, in order to prey on young seals, which they catch asleep; but this repast sometimes proves fatal to them, for the ice, detached from the shore, carries them to a great distance from the land before they are sensible of it. It is said that in some years a large district is by this means delivered from these pernicious beasts, which are heard howling in a most dreadful manner far in the sea.

The time of gestation in the wolf is, according to Buffon, about three months and a half; and the young whelps are found from April to July; and this difference in the time of gestation, which in the wolf is 100 days, and in the dog only 60, he considers justly as a proof of the real difference between the two species. See Plate XXVI. Nat. Hist. fig. 34.

3d. Canis Mexicanus, or Mexican wolf, appears to have been first described by Hernandez, in his account of Mexico. In its general appearance it resembles the common wolf, but has a head twice as large, a thicker neck, and a less bushy tail: the colour of the body is cinereous, marked with some yellow spots. Above the mouth are situated several bristles as large, but not so stiff, as those of the hedgehog; the ears are gray, like the head and body; there is a long yellow spot on the neck, another on the breast, and a third on the belly; on the flanks are transverse bands from the back to the belly; the tail is gray, with a yellow spot in the middle; the legs are barred with gray and brown.

4th. Canis lycaon, or black wolf. Like the common wolf, it is found both in Europe and America, as well as in some parts of Asia. It bears a great general resemblance to the common species, but is smaller, entirely black, with a somewhat thinner or less bushy tail hanging nearly straight; the ears are larger in proportion than those of the common wolf, and the eyes smaller, and situated at a greater distance from each other. In America the black wolf is chiefly found in Canada, and in Europe occurs only in the more northern regions.

5th. Canis hyæna, is a native of many parts of Asia and Africa, being found in Syria, Persia, Barbary, Senegal, &c. Its general size is that of a large dog, but it is distinguished by great strength of limbs, and by a remarkable fulness or thickness of the snout. Its colour is a pale grayish brown, accompanied by a tawny cast, and the whole body is marked by several distant blackish transverse bands running from the back downward. On all the feet are four toes. Hyænas generally inhabit caverns and rocky places: they prowl about chiefly by night, and feed on the remains of dead animals as well as on living prey. They are even said to devour the bodies which they occasionally find in cemeteries. They attack cattle, and frequently commit great devastation among the flocks. Though not gregarious from any social principle, they sometimes assemble in troops, and follow with dreadful assiduity the movements of an army, through the hope of feasting on the slaughtered bodies. See Plate XXVI. Nat. Hist. fig. 79.

There is something in the aspect of the hyæna which seems to indicate a peculiar gloominess and malignity of disposition; and its manners in a state of captivity seem in general to correspond with its appearance, being savage and untractable. It has even been supposed that the hyæna cannot be tamed; but this opinion is proved to be erroneous from two instances at least; one of which is recorded by Mr. Pennant, who declares that he saw a hyæna which had been rendered as tame as a dog; the other by the Count de Buffon, who assures us that in an exhibition of animals at Paris, in the year 1773, there was a hyæna which had been tamed very early, and was apparently divested of all its natural malevolence of disposition.

6th. Canis crocuta, or spotted hyæna, resembles the former, but is superior in size, and is readily distinguished by being marked all over the body and legs with numerous roundish black spots. It is an African animal, and is found in Guinea, Ethiopia, and about the Cape of Good Hope.

7th. Canis aureus, or jackal, is a native of the warmer regions of Asia and Africa, and appears to be no where more common than in Barbary. It is about the size of a middling dog, and is of a pale or light orange yellow, with darker or blackish shades about the back and legs: the tail hangs straight, is rather bushy, and is commonly black at the tip. The jackal resides in rocky places, and in woods, and makes its principal excursions during the night, preying indiscriminately on all the weaker animals. It also occasionally devours various vegetables. The voice of the jackal is described as peculiarly hideous, consisting of a kind of mixture of howling and indistinct barking. These animals frequently go in great troops to hunt their prey, and by their dreadful yellings alarm and put to flight deer, antelopes, and other timid quadrupeds; while the lion, instinctively attending to the clamour, is said to follow till the jackals have hunted down the prey, and, having satiated himself, leaves only the mangled remains to be devoured by the jackals.

When taken young the jackal is easily tamed, attaches itself to mankind, distinguishes its master, comes on being called by its name, shows an attachment to dogs, instead of flying from them, and has all the other particularities of character by which the dog is distinguished. See Plate XXVI. Nat. Hist. fig. 82.

8th. Canis mesomelas, or cape jackal, is said to be not uncommon about the Cape of Good Hope, and is by some confounded with the jackal, to which, indeed, it seems to be very nearly allied. The head is yellowish brown, with a mixture of black and white hairs: the nape of the neck and the whole length of the back black, with a mixture of white. The general colour of the animal is bright foxy or ferruginous: the tail is not unlike that of a fox, but rather less bushy. The length of this animal is two feet and three quarters, exclusive of the tail, which measures one foot.

9th. Canis Barbarus, Barbary jackal, has a long slender nose, sharp upright ears, and a long bushy tail. Its colour

is a very pale brown: from behind each ear runs a black line, which soon divides into two, running downward along the neck. It is of the size of the common fox, but the limbs seemingly shorter, and the nose more slender.

10th. Canis Ceilonicus, Ceylonese dog, is a native of Ceylon, but no particulars relative to its manners or history are known. It is a little larger than a common domestic cat, measuring about twenty-two inches from nose to tail; the tail itself sixteen inches, gradually tapering to the point. The claws of this animal resemble those of a cat more than of a dog, though not so long and slight in proportion. Both fore and hind feet have five toes.

11th. Canis vulpes, or fox, like the wolf, appears to be pretty generally diffused throughout all the northern and temperate parts of the globe; occurring with numerous varieties, as to shades of colour and gradations of size, in most parts of Europe, the north of Asia, and America. See Plate XXVI. Nat. Hist. fig. 33.

In the northern climates are foxes of all colours, black, blue, gray, iron colour, silver gray, white with yellow feet, white with black heads, white with the extremity of the tail black, reddish, with the throat and belly entirely white, and, lastly, some have a black line along the back, and crossed with another over the shoulders: the latter are larger than the other kinds, and have black throats.

The fox prepares for himself a convenient den or receptacle in which he lies concealed during the greater part of the day. This den is sometimes said to be obtained by dispossessing the badger of its hole, and appropriating it to his own purposes. It is so contrived as to afford the best security to the inhabitant, by being situated under hard ground, the roots of trees, &c. and is besides furnished with proper outlets through which he may escape in case of necessity.

The fox attempts his prey by cunning rather than by force: his scent is exquisite, so that he can perceive his prey or his enemies at the distance of 2 or 300 paces: he has the habit of killing more than he eats, and hiding the remainder under grass, the roots of trees, &c. His voice is a sharp, quick yell, often ending in a higher, stronger, and screaming kind of note, not unlike that of the peacock.

The fox produces five or six young at a time; and if they are discovered or disturbed, the female will carry them in her mouth, one at a time, to some more secret retreat; in this respect imitating the conduct of the cat and dog, which are known to do the same.

12th. Canis alopex, brant fox, is less than the common fox, and has a thicker and darker fur, though sometimes, on the contrary, it is much brighter and redder than that species, as mentioned by Linnæus in his Fauna Suecica: the tail is tipped with black.

13th. Canis corsac, or corsac fox. The colour of this species is, in summer, a clear yellow ferruginous; in winter mixed or shaded with gray, deeper on the back, white on the belly, and reddish on the feet: the eyes are surrounded with a border of white; and a brownish stripe runs from them down the nose. The size of this animal is less than that of the common fox.

14th. Canis Karagan, or Karagan fox. This is a small species, which, according to Dr. Pallas, is very common in almost all parts of the Kirghisian deserts and Great Tartary. Its general colour is a wolf gray; the head yellowish, and above the eyes reddish: the throat and breast are of a deep or blackish gray, the belly white.

15th. Canis cinereo argenteus, or fulvous necked fox, inhabits North America, and the skins are often sent over to Europe. The crown of the head, neck, and back, are gray, mixed with black and white: the finer hairs being white gray, the coarser varied with black and white like a porcupine's quill. In size this species is inferior to the common fox.

16th. Canis Virginianus, or Virginian fox, resembles the common fox in shape: has a sharp nose, long, sharp, upright ears, long legs, and a bushy tail: its colour is a whitish gray, with a cast of red about the ears. It inhabits the warmer parts of North America, particularly Carolina and Virginia. It is said never to burrow under ground like the common fox, but to inhabit hollow trees: it is destitute of the strong smell of the common fox, is easily tamed, and is said to prey chiefly on poultry, birds, &c.

17th. Canis argentatus, silvery fox, resembles the common fox. It is of a deep brown colour, with the longer or exterior hairs of a silvery white, giving a highly elegant appearance to the animal. It is an inhabitant of the forests of Louisiana, and preys on game.

18th. Canis lagopus, arctic fox, is inferior in size to the common fox. Its colour is a bluish gray, which sometimes changes to perfect white: when young it is said to be of a dusky colour. They inhabit Spitzbergen, Greenland, and Iceland; and are only migratory in Hudson's Bay, once in four or five years. They are the hardiest of animals, and even in Spitzbergen and Nova Zembla prowl for prey during the severity of winter. They live on the young wild geese, and all kinds of water fowl, or on their eggs; on hares or any lesser animals; and in Greenland, through necessity, on berries, shell fish, or whatsoever the sea throws up. They swim well, and often cross from island to island in search of prey. The Greenlanders take them either in pitfalls dug in the snow, and baited with the capelin fish, or in springs made with whalebone laid over a hole made in the snow, strewed over at bottom with the same kind of fish; or in traps made like little huts, with flat stones, with a broad one by way of door, which falls down, by means of a string baited on the inside with a piece of flesh, whenever the fox enters and pulls at it. The Greenlanders preserve the skin for traffic; and, in cases of necessity, eat the flesh. They also make buttons of the skins; and split the tendons, which they use instead of thread. The blue furs are much more esteemed than the white. See Plate XXV. Nat. Hist. fig. 30.

19th. Canis culpæus, Chili fox, is supposed to be a variety of the antarctic fox. Its length from nose to tail is two feet and a half; its colour a deep brown. It inhabits the open countries of Chili, in which it forms its burrows.

20th. Canis thous, or Surinam dog, seems to have been unknown to other naturalists. Linnæus states only that the body is gray, entirely white beneath; that it is of the size of a large cat, and has upright ears of the same colour with the body; a verruca or wart above the eyes, on each cheek, and beneath the throat; and that the tongue is ciliated at the edges.

21st. Canis Bengalensis, Bengal fox, is scarcely half the size of the European fox. The face is cinereous, the body pale brown, the legs fulvous, the tail tipped with black, and down the middle of the face runs a black stripe. The spaces round the eyes and the middle of the jaws are white. It is said to feed chiefly on roots and berries.

22d. Canis fuliginosus, sooty fox, in size and habit resembles the arctic fox, but is a distinct species. It is said to be numerous in Iceland.

23d. Canis antarcticus, antarctic fox, is about a third part superior in size to the arctic fox, and has pretty much the habit of a wolf in its ears, tail, and strength of limbs. It is a native of the Falkland isles, and is said to be almost the only land quadruped of those distant spots. It resides near the shores; kennels like a fox, and forms regular paths from bay to bay, probably for the convenience of surprising water fowl, on which it principally lives. It is a tame, fetid animal, and barks in the manner of a dog.

24th. Canis zerda, the Fennec, or zerda, is a beautiful African and Asiatic animal, and is principally found in Arabia. Its general length is about ten inches, and its colour yellowish white. The ears, which are uncommonly large, are internally of a bright rose colour, edged with a broad margin of white hair, and the tip of the tail is black. It inhabits the vast deserts of Zaara, which extend beyond mount Atlas; it burrows in sandy ground, which shows the use of valves to the ears. It is so exceedingly swift that it is very rarely taken alive; feeds on insects, especially locusts; sits on its rump; is very vigilant, and barks like a dog, but much shriller.

Canis *major*, in astronomy, a constellation of the southern hemisphere, consisting of 28 stars, according to Ptolemy; of 13, according to Tycho; and 32 in the Britannic catalogue.

Canis *minor*, Canicvlus, or Canicula, in astronomy, a constellation of the northern hemisphere. In Ptolemy's catalogue, the canis minor comprehends two stars; in that of Tycho, five; and in the Britannic catalogue, 15.

CANNA, Indian flowering reed; a genus of the monogynia order, in the monandria class of plants; and in the natural method ranking under the 8th order, scitaminæ. The corolla is erect, and divided into six parts, with a distinct lip, bipartite, and rolled back; the style lanceolate, and growing to the corolla; the calyx is triphyllous. There are five species, *viz.*

1. Canna coccinea, has larger leaves than any of the other four species, and the stalks rise much higher. The flowers are produced in large spikes, and are of a bright crimson or rather scarlet colour.

2. Canna glauca, with a very large yellow flower, is a native of South America.

3. Canna Indica, or common broad leaved flowering cane.

4. Canna latifolia, with a pale red flower, is a native of Carolina, and some other northern provinces of America.

5. Canna lutea, with obtuse oval leaves, is less common in America than the other sorts. All these plants must always be kept in pots of rich earth, to be moved to shelter in winter.

CANNABIS, *hemp*, in botany, a genus of the dioecia pentandria class of plants, and in the natural method ranking under the 53d order, scabridæ. The calyx of the male is quinquepartite, with no corolla. In the female the calyx is monophyllous, entire, and gaping at the side; there is no corolla, but two styles; the fruit is a nut, bivalved, within the closed calyx. Of this there is but one species, *viz.*

Cannabis sativa. It is propagated in the rich fenny parts of Lincolnshire in great quantities for its bark, which is useful for cordage, cloth, &c. and the seeds abound with oil. Hemp is always sown on a deep, moist, rich soil, such as is found in Holland, Lincolnshire, and the fens of the island of Ely, where it is cultivated to great advantage, as it might be in many other parts of England where there is a soil of the same kind; but it will not thrive on clayey or stiff cold land. The ground on which hemp is to be sown should be well ploughed, and made very fine by harrowing. About the middle of April the seed may be sown; three bushels are the usual allowance for an acre, but two are sufficient. In the choice of the seed, the heaviest and brightest coloured should be preferred; and particular care should be had to the kernel of the seed. For the greater certainty in this matter, some of the seeds should be cracked to see whether they have the germ or future plant perfect; for, in some places, the male plants are drawn out too soon from the female, *i.e.* before they have impregnated the female plants with the farina; in which case, though the seeds produced by these females may seem good to the eye, yet they will not grow. When the plants are come up, they should be hoed out in the same manner as turnips, leaving them two feet apart; observe also to cut down all the weeds, which, if well performed, and in dry weather, will destroy them. This crop, however, will require a second hoeing, in about six weeks after the first; and, if this is well performed, the crop will require no further care. The first season for pulling hemp is usually about the middle of August, when they begin to pull what they call the *simple hemp*, being that which is composed of the male plants; but it would be much better to defer this for a fortnight or three weeks longer, until those male plants have fully shed their farina or dust, without which the seeds will prove only empty husks. These male plants decay soon after they have shed their farina. The second pulling is a little after Michaelmas, when the seeds are ripe. This is usually called *karle hemp*, and consists of the female plants which were left. This karle hemp is bound in bundles of a yard compass, according to the statute measure, which are laid in the sun for a few days to dry; and then it is stacked up or housed to keep it dry till the seed can be threshed out. An acre of hemp, on a rich soil, will produce nearly three quarters of seed, which, together with the unwrought hemp, are worth from 6*l.* to 8*l.* Hemp is esteemed very effectual for destroying weeds; but this it accomplishes by impoverishing the ground, and thus robbing them of their nourishment; so that a crop of it must not be repeated on the same spot.

CANNEL COAL. See Ampelites.

CANNON, in the military art, an engine or kind of fire arms for throwing iron, lead, or stone bullets, by the force of gunpowder.

Cannons at first were called bombardæ, from the noise they made. They had likewise the name of culverin, basilisk, &c. from the beasts that were represented upon them; and the Spaniards, from devotion, gave them the

name of saints; witness the twelve apostles which Charles V. ordered to be cast at Malaga, for his expedition to Tunis.

The most remarkable parts about a cannon are the cascabel, mouldings, base ring, touch-hole, vent ring, reinforced ring, trunnions, dolphins, trunnion ring, cornish ring, neck, muzzle, face, and chase or cylinder.

The metal of which brass cannon is made is in a manner kept a secret by the founders; yet, with all their art and secrecy, they have not hitherto found out a composition that will stand a hot engagement without melting, or being rendered useless. Those cast at Woolwich bid fairest toward this amendment. The respective quantities which should enter into this composition, is a point not decided; every founder has his own proportions, which are peculiar to himself. The most common proportions of the ingredients are the following, *viz.* To 240lb. of metal fit for casting, they put 68lb. of copper, 52lb. of brass, and 12lb. of tin. To 4200lb. of metal fit for casting, the Germans put 3687$\frac{3}{4}\frac{3}{1}$lb. of copper, 204$\frac{1}{4}\frac{3}{1}$lb. of brass, and 307$\frac{3}{4}\frac{6}{1}$lb. of tin. Others again use 100lb. of copper, 6lb. of brass, and 9lb. of tin: and lastly, others 100lb. of copper, 10lb. of brass, and 15lb. of tin. With respect to iron guns, their structure is the same as that of the others, and they generally stand the most severe engagements, being frequently used on ship board. Several experiments have taught us that the Swedish iron guns are preferable to all others.

Cannons are distinguished by the diameters of the balls they carry. The rule for their length is, that it be such as that the whole charge of powder be on fire before the ball quits the piece. If it be too long, the quantity of air to be driven out before the ball, will give too much resistance to the impulse; and that impulse ceasing, the friction of the ball against the surface of the piece will take off from the motion.

In former days, cannon were made much longer than they are now; but experience has taught us, that a ball moves with a greater impetus through a less space than a greater: and accordingly it is found that an iron ball of 48 pounds weight goes further from a short cannon than another ball of 96 pounds out of a longer piece; whereas, in other respects, it is certain, the larger the bore and ball, the greater the range. But for the range of a cannon, see Projectile. It is found, too, by experience, that of two cannons of equal bore, but different lengths, the longer requires a greater charge of powder than the shorter. The ordinary charge of a cannon is, for the weight of its gunpowder to be half that of its ball. See Founding.

CANON, in an ecclesiastical sense, a law, rule, or regulation, of the policy and discipline of a church, made by councils, either general, national, or provincial.

Canons *of the apostles*, a collection of ecclesiastical laws, which, though very ancient, were not left us by the apostles. It is true, they were sometimes called apostolic canons; but this means no more than that they were made by bishops who lived soon after the apostles, and were called apostolical men. They consist of regulations, which agree with the discipline of the second and third centuries. The Greeks generally count eighty-five, but the Latins receive only fifty, nor do they observe all these.

Canon *of mass*, in the Romish church, the name of a prayer which the priest reads low to himself, the people kneeling.

Canon, in arithmetic, algebra, &c. is a rule to solve all things of the same nature with the present inquiry; thus, every last step of an equation in algebra, is such a canon; and, if turned into words, is a rule to solve all questions of the same nature with that proposed.

The tables of logarithms, artificial sines and tangents, are called likewise by the name of canon.

Canon *law*, a collection of ecclesiastical laws, serving as the rule and measure of church government. The power of making laws was exercised by the church before the Roman empire became Christian. The canon law that obtained throughout the west, till the twelfth century, was the collection of canons made by Dionysius Exiguus in 520, the capitularies of Charlemagne, and the decrees of the popes, from Sircius to Anastasius.

The canon law, even when papal authority was at its height in England, was of no force when it was found to contradict the prerogative of the king, the laws, statutes, and customs of the realm, or the doctrine of the established church. The ecclesiastical jurisdiction of the see of Rome in England, was founded on the canon law; and this created quarrels between kings and several archbishops and prelates, who adhered to the papal usurpation. Besides the foreign canons, there were several laws and constitutions made here for the government of the church; but all these received their force from the royal assent; and if, at any time, the ecclesiastical courts did, by their sentence, endeavour to enforce obedience to such canons, the courts at common law, upon complaints made, would grant prohibitions. The authority vested in the church of England of making canons was ascertained by a statute of Henry VIII. commonly called the act of the clergy's submission; by which they acknowledged that the convocation had been always assembled by the king's writ; so that though the power of making canons resided in the clergy met in convocation, their force was derived from the authority of the king's assenting to, and confirming them. The old canons continued in force till the reign of James I. when the clergy being assembled in convocation, the king gave them leave to treat and consult upon canons, which they did, and presented them to the king, who gave them the royal assent. These were a collection out of the several preceding canons and injunctions. Some of these canons are now obsolete. In the reign of Charles I. several canons were passed by the clergy in convocation.

CANOPUS, in astronomy, a star of the first magnitude in the rudder of Argo, a constellation of the southern hemisphere.

CANTAR, or Cantaro, in commerce, a weight used in Italy, particularly at Leghorn. There are three sorts: one weighs 150 pounds, the other 151, and the third 160. The first serves to weigh alum and cheese; the second is for sugar; and the third for wool and cod fish. The word is used also as a measure of capacity used at Cochin, and containing four rubis.

CANTATA, in music, a song or composition, intermixed with recitatives, airs, and different movements, chiefly intended for a single voice.

CANTEENS, tin or wooden vessels used by soldiers on a march, &c. to carry water or other liquor in; each

holds about two quarts. Wooden canteens are in general use with the British army: they are made cylindrical, like barrels, 7½ inches in diameter, and about four inches in length. They are chiefly manufactured by Mr. George Smart, of Camden Town.

CANTHARIS, in zoology, a genus of coleopterous insects, with setaceous antennæ, the exterior wings of which are flexile, the thorax somewhat flatted, and the sides of the abdomen plicated. Linnæus enumerates 27 species of the cantharis, most of them to be found in different parts of Europe.

For the cantharis, usually called Spanish flies with us, see MELOE.

CANTHI. See ANATOMY.

CANTO, in music, the treble, or at least the higher part of a piece.

CANTONED, in architecture, is when the corner of a building is adorned with a pilaster, an angular column, rustic quoins, or any thing that projects beyond the naked of a wall.

CANTONED, or CANTONIZED, *cantonée*, in heraldry, the position of such things as are borne with a cross, &c. between. He bears gules, a cross argent cantoned with four scallop shells.

CANTRED, or CANTREF, signifies an hundred villages; being a British word, compounded of the adjective *cant*, *i.e.* hundred, and *tref*, a town or village. In Wales, some of the counties are divided into cantreds, as in England into hundreds.

CANTUA, in botany, a genus of the tetrandria class, monogynia order: the essential characters are; cal. five parted, cor. five parted, colour red, capsule ovate. There are two species; 1. C. coronopifolia, scarlet cantua, flowers in August, frutescent, biennial. 2. C. inconspicua, blue buck's horn leaved cantua, cor. blue, flowers in November, both natives of Florida and Carolina.

CANVAS, in commerce, a very clear unbleached cloth of hemp or flax, woven very regularly in little squares. It is used for working tapestry with the needle, by passing the threads of gold, silver, silk, or wool, through the intervals or squares. It is also a coarse cloth of hemp, unbleached, somewhat clear, which serves to cover women's stays, also to stiffen men's clothes, and to make some other of their wearing apparel, &c. It is also used to make sails for shipping, &c.

CANZONE, in music, signifies in general a song where some little figures are introduced; and

CANZONETTA is a diminutive of the same.

CAOUTCHOUC. About the beginning of the 18th century, a substance called caoutchouc was brought as a curiosity from America. It was soft, very elastic, and combustible. The pieces of it that came to Europe were usually in the shape of bottles, birds, &c. This substance is very much used in rubbing out the marks made upon paper by a blacklead pencil; and therefore in this country it is often called Indian rubber. Nothing was known of its production, except that it was obtained from a tree, until the French academicians went to South America in 1735, to measure a degree of the meridian. Mr. de la Condamine sent an account of it to the French academy, in the year 1736. He told them, that there grew in the province of Esmeraldas, in Brazil, a tree, called by the natives *hhevé*; that from this tree there flowed a milky juice, which, when inspissated, was caoutchouc.

It is now known that there are at least two trees in South America, from which caoutchouc may be obtained; the hævea caoutchouc and the jatropha elastica: and it is exceedingly probable that it is extracted also from other species of hævea and jatropha. Several trees, likewise, which grow in the East Indies, yield caoutchouc. When any of these plants is punctured, there exudes from it a milky juice, which, when exposed to the air, gradually lets fall a concrete substance, which is caoutchouc.

If oxymuriatic acid is poured into the milky juice, the caoutchouc precipitates immediately, and, at the same time, the acid loses its peculiar odour. This renders it probable that the formation of the caoutchouc is owing to its basis absorbing oxygen. If the milky juice is confined in a glass vessel containing common air, it gradually absorbs oxygen, and a pellicle of caoutchouc appears on its surface.

Caoutchouc, when pure, is of a white colour, and without either taste or smell. The blackish colour of the caoutchouc of commerce, is owing to the method employed in drying it after it has been spread upon moulds. The usual way is to spread a thin coat of the milky juice upon the mould, then to dry it by exposing it to smoke; afterward another coat is spread on, which is dried in the same way. Thus the caoutchouc of commerce consists of numerous layers of pure caoutchouc alternating with as many layers of soot. It is soft and pliable; it is exceedingly elastic and adhesive; so that it may be forcibly stretched out much beyond its usual length, and instantly recover its former bulk when the force is withdrawn. It cannot be broken without very considerable force. Its specific gravity is 0.9335. It is not altered by exposure to the air; it is perfectly insoluble in water; but if boiled for some time, its edges become somewhat transparent, owing undoubtedly to the water carrying off the soot; and so soft, that when two of them are pressed and kept together for some time, they adhere as closely as if they formed one piece. By this contrivance pieces of caoutchouc may be soldered together, and thus made to assume whatever shape we please. Caoutchouc dissolved in ether may be employed to make instruments of different kinds, just as the milky juice of the hævea; but this method would be a great deal too expensive for common use.

Caoutchouc is soluble in volatile oils; but, in general, when these oils are evaporated, it remains somewhat glutinous; and therefore is scarcely proper for those uses to which, before its solution, it was so admirably adapted. It is also soluble in alkalies. When exposed to heat it readily melts; but it never afterward recovers its properties, but continues always of the consistence of tar. It burns very readily with a bright white flame, and diffuses a fetid odour. In the countries where it is found, it is frequently used by way of candle. When distilled it gives out ammonia: from this, and from the effect of sulphuric and nitric acid upon it, there is no doubt that it is composed of carbon, hydrogen, azote, and oxygen; but the modes of their combination are unknown.

CAP *of maintenance*, one of the regalia or ornaments of state belonging to the kings of England, before whom

it was carried at the coronation, and other great solemnities. Caps of maintenance are also carried before the mayors of the several cities in England.

Cap, in a ship, a square piece of timber put over the head or upper end of any mast, having a round hole to receive the mast. By means of these caps, the topmasts and top-gallantmasts are kept steady and firm in the tressel trees where their feet stand.

Cap *of a gun*, a piece of lead which is put over the touch-hole of a gun, to keep the priming from being wasted or spoiled.

CAPE, in law, a judicial writ concerning plea of lands or tenements, and divided into cape magnum and cape parvum, both of which affect things immoveable; and besides these there is a cape *ad valenciam*.

Cape *magnum*, is designed to lie where a person has brought a *præcipe quod reddat* of a thing that touches a plea of land, and the tenant makes default at the day given to him in the original writ; then this writ shall go for the king, to take the land into his hands: and if he comes not at the day given him, he loses his land, &c.

Cape *parvum*, called petit cape, is defined thus: when the tenant is summoned in plea of land, and cometh at the summons, and his appearance is recorded; and after he maketh default at the day that is given to him, then this writ shall go for the king.

Cape *ad valenciam*, is a species of cape *magnum*, where one being impleaded, and on a summons to warrant lands, a vouchee does not come at the day; whereupon if the demandant recovers of the tenant, he shall have this writ against the vouchee, and recover so much in value of his lands, in case he has so much; and if not, there shall be an execution of such lands and tenements as shall after descend to him in fee; or if he purchases, afterward, there may be a regular summons, &c. against him.

CAPELLA, in astronomy, a bright fixed star in the left shoulder of the constellation Auriga. It is, in the Britannic catalogue, the fourteenth in order of that constellation. Its longitude is 17° 31′ 41″; its latitude 22° 51′ 47″.

CAPER. See Capparis.

CAPHAR, a duty which the Turks raise on the Christians who carry or send merchandises from Aleppo to Jerusalem and other places in Syria.

CAPI AGA, or Capou agassi, a Turkish officer, who is grand master of the seraglio.

CAPIAS, in law, is a writ of two sorts, one whereof is called *capias ad respondendum*, *before* judgment; where an original is sued out, &c. to take the defendant and make him answer the plaintiff: and the other a writ of execution, *after* judgment, being of divers kinds.

Capias *ad respondendum*, is a writ commanding the sheriff to take the body of the defendant, if he may be found in his bailiwic, or county, and him safely to keep, so that he may have him in court on the day of the return, to answer to the plaintiff of a plea of debt or trespass, or the like, as the case may be. And if the sheriff return that he cannot be found, then there issues another writ, called an *alias capias;* and after that another, called a *pluries capias;* and if upon none of these he can be found, then he may be proceeded against to outlawry. But all this being only to compel an appearance, after the defendant has appeared the effect of these writs is taken off, and the defendant shall be put to answer, unless in cases where special bail is required, and there the defendant is actually to be taken into custody. 3 Blacks. 212.

Capias *ad satisfaciendum*, is a writ directed to the sheriff, commanding him to take the body of the defendant, and him safely to keep, so that he may have his body in court at the return of the writ, to make the plaintiff satisfaction for his demand: otherwise he is to remain in custody till he does. When a man is once taken in execution upon this writ, no other process can be sued out against his lands or goods. But if a defendant dies whilst charged in execution upon this writ, the plaintiff may, after his death, sue out new executions against his lands, goods, or chattels. 3 Blacks. 415.

Capias *utlegatum*, is a writ that lies against a person that is outlawed in any action, whereby the sheriff is commanded to apprehend the body of the party outlawed, and keep him in safe custody till the day of the return of the writ, and then present him to the court, there to be dealt with for his contempt. But this being only for want of appearance, if he shall afterward appear, the outlawry is most commonly reversed. 3 Blacks. 284.

Capias *in withernam*, is a writ directed to the sheriff, in case where a distress is carried out of the county, or concealed by the distrainer, so that the sheriff cannot make deliverance of the goods upon a replevin; commanding him to take so many of the distrainer's own goods, by way of reprisal, instead of the other that are so concealed.

CAPILLARY *tubes*, in physics, little pipes, whose canals are extremely narrow, their diameter being only a half, third, or fourth of a line. See Attraction.

Capillary *vessels*. See Anatomy.

CAPISTRUM. See Surgery.

CAPITAL, in architecture, the uppermost part of a column or pilastre, serving as the head or crowning, and placed immediately over the shaft, and under the entablature. See Architecture.

CAPITATION, a tax or imposition raised on each person in consideration of his labour, industry, office, rank, &c. commonly called a poll tax.

CAPITULATION, in the German polity, a contract which the emperor makes with the electors in the name of all the princes and states of the empire, before he is declared emperor, and which he ratifies before he is raised to that sovereign dignity. The principal points which the emperor undertakes to observe, are, 1. To defend the church and the empire. 2. To observe the fundamental laws of the empire. 3. To maintain and preserve the rights, privileges, and immunities, of the electors, princes, and other states of the empire, specified in the capitulation. These articles and capitulations are presented to the emperor by the electors only, without the concurrence of the other states, who have complained from time to time of such proceedings: and in the time of the Westphalian treaty, in 1648, it was proposed to deliberate in the following diet upon a way of making a perpetual capitulation; but the electors have always found means of eluding the execution of this article. In order, however, to give some satisfaction to their adversaries, they have inserted in the capitulations of the emperors, and in that of Francis I. in particular, a promise to use all their influence to bring the affair of a perpetual capitulation to a conclusion. Some German authors own that this capitulation limits

the emperor's power; but maintain, that it does not weaken his sovereignty: though the most part maintain, that he is not absolute, because he receives the empire under conditions, which sets bounds to an absolute authority.

CAPOC, a sort of cotton as soft as silk, so fine and so short that it cannot be spun. It is used in the East Indies, as well as in Europe, to line palanquins, to make beds, mattresses, cushions, pillows, &c.

CAPONIERE, or CAPONNIERE, a work sunk on the glacis of a place, about four or five feet deep. The earth that comes out of it serves to form a parapet of two or three feet high, made with loopholes or small embrasures: it is covered over head with strong planks, on which are laid clays or hurdles, which support the earth that covers all. It holds 15 or 20 men, who fire through these embrasures. They are also sometimes made in the bottom of a dry moat.

CAPPADINE, a sort of silk flock, taken from the upper part of the silkworm cod, after the true silk has been wound off.

CAPPARIS, a genus of the monogynia order, in the polyandria class of plants, and in the natural method ranking under the 25th order, putamineæ. The calyx is tetraphyllous and coriaceous; the petals are four, the stamina are long; the fruit is a berry, carnous, unilocular, and pedunculated, or furnished with a footstalk. There are 25 species, of which the principal is,

Capparis spinosa, or common caper, a low shrub, generally growing out of the joints of old walls or fissures of rocks in the warm parts of Europe. This plant is with great difficulty preserved in England. The pickle made from its berry is well known.

CAPRA, the GOAT KIND, in zoology, constitutes a genus of quadrupeds of the order of pecora. The generic character is, horns hollow, turning upward and backward, compressed, rough, almost close at their base. Front teeth in the lower jaw eight. Canine teeth, or tusks, none. Chin bearded in the male. There are nine species and varieties:

1. CAPRA IBEX. This, which is the common ibex or steinbock of authors, appears to have been sometimes confounded with the Caucasan ibex, or next species, to which it is much allied. It is found in several parts of Europe and Asia. It inhabits the Carpathian and Pyrenean mountains, and various parts of the Alps, more particularly the Rhætian Alps, in the midst of snow and glaciers. In Asia it occurs on the summits of the chain of mountains extended from Taurus, and continued between eastern Tartary and Siberia. It also inhabits the tract beyond the Lena, and in all probability may be a native of Kamtschatka. In Arabia it inhabits the province of Hedsjaes, and is there known by the name of Baeden. Lastly, it is found in the high mountains of the island of Crete, where the Caucasan ibex has also been discovered.

It is an animal of great strength and agility, and is considerably larger than a common domestic goat. Its colour is a deep hoary or grayish brown; much paler or whitish beneath, and on the insides of the limbs; the body is of a thick, strong form; the head rather small, the eyes large, and the horns extremely large and long, so as sometimes to measure three feet in length, and to extend the whole length of the body.

In its general habits or manners the ibex resembles the common goat; but possesses every attribute of strength and activity in a degree proportioned to its natural state of wildness. It is even said, that, when hard pressed, this animal will fling itself down a steep precipice, and falling on its horns, escape unhurt from its pursuers; nor will this appear in the least incredible, if we may rely on the faith of Monardes, who assures us that he saw a Caucasan ibex leap from the top of a high tower, and falling on its horns, immediately spring up on its limbs, and leap about without having received the least apparent injury. See Plate XXVI. Nat. Hist. fig. 90.

The flesh of the young ibex is said to be in good esteem as an article of food. Its period of gestation is said to be the same as in the common goat, *viz.* five months.

2. CAPRA ÆGAGRUS, or CAUCASAN IBEX, supposed to be the stock or origin of the domestic goat, is considerably superior to that animal in size, and its form in some degree resembles that of a stag. Its general colour is a brownish or subferruginous gray above, and white beneath; the forehead is nearly black, which colour is continued down the back in the form of a list or stripe: the chin is furnished with a large brownish beard, and the horns, which are very large, and bend considerably backward, are smooth, black, and sharply ridged on their upper part. The female is destitute both of horns and beard.

In point of strength and agility this species is at least equal, if not superior, to the common ibex; it inhabits the loftiest rocky points of mount Caucasus, and particularly the parts about the rivers Kuban and Terek; almost all Asia Minor, and may probably extend even to India. It is said to abound on the hills of Laar and Chorazan, in Persia.

3. CAPRA HIRCUS, or COMMON GOAT, in its domestic state, is found in almost every part of the globe, bearing the extremes of heat and cold, and differing in size and form according to various circumstances. It may be observed, that the horns have generally a curvature outward toward the tips; and it may be added, that the animal was entirely unknown to the Americans on the discovery of that continent, having been introduced by the Europeans.

The colour of the domestic goat is various, being either black, brown, white, or spotted. The flesh is of great use to the inhabitants of Wales, and affords them a cheap and plentiful provision in the winter months, when the kids are brought to market: the haunches are often dried and salted, and used as a substitute for bacon. The skin of the goat is peculiarly well adapted for the glove manufactory, especially that of the kid; and as it takes a dye better than any other skin, it was formerly much used for hangings in the houses of people of fortune; being susceptible of the richest colours. The goat goes with young four months and a half. The skin of the Chamois goat is also in high esteem for fine leather. See Plate XXVI. Nat. Hist. fig. 91.

The following are the most remarkable varieties of the domestic goat.

1. Capra mambrica, or Syrian goat, is distinguished by the great length of the ears, which are pendulous, like those of a hound, and sometimes reach so low as to be troublesome to the animal while feeding. 2. Capra Angorensis, Angora goat, is generally of a beautiful milk white colour, short legged, with black, spreading, spirally twisted

horns, and with the hair on the whole body disposed in long pendent spiral ringlets. It is from the hair of this animal that the finest camlets, &c. are prepared. 3. Capra depressa, or African goat, is a very small or dwarf variety, found in some parts of Africa. 4. Capra reversa, or Whidaw goat. This is also a dwarf variety, found in Africa, where its flesh is considered as an excellent food. 5. Long horned Whidaw goat. 6. Capricorn goat.

CAPRARIA, Sweet weed, a genus of the angiospermia order, in the didynamia class of plants; and in the natural method ranking under the 40th order, personatæ. The calyx is quinquepartite; the corolla is campanulated, quinquefid, with acute segments; the capsule bivalved, bilocular, and polyspermous. There are five species.

CAPRICORN, in astronomy, one of the twelve signs of the zodiac, represented in globes in the form of a goat, and characterized in books by this mark ♑.

It is the tenth sign in order, and contains twenty-eight stars according to Ptolemy and Tycho Brahe; twenty-nine according to Hevelius; and fifty-one according to Flamsteed.

Tropic of Capricorn, a lesser circle of the sphere, which is parallel to the equinoctial, and at 23° 30′ distance from it southward.

CAPRIMULGUS, goat sucker, a genus of birds belonging to the order of passeres. The beak is incurvated, small, tapering, and depressed at the base: the mouth opens wide. There are two species: 1. The Europæus, with the tubes of the nostrils hardly visible, which feeds on moths, gnats, &c. It appears in May, and leaves us in August. 2. The Americanus, a night bird, found in America. See Plate XXV. Nat. Hist. fig. 81.

CAPSICUM, in botany, Guinea pepper, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 28th order, luridæ. The corolla is verticillated, and the fruit is a sapless berry. There are five species; the principal are:

1. Capsicum annuum, the common long podded capsicum, commonly cultivated in the gardens. Of this there is one variety with red, and another with yellow fruit; and of these there are several subvarieties, differing only in the size and figure of their fruit.

2. Capsicum baccatum, bird pepper, rises with a shrubby stalk four or five feet high; the leaves are of a lucid green; the fruit grows at the division of the branches, standing erect: these are small, oval, and of a bright red: they are much more sharp and biting than those of the other sorts. This is the Cayenne pepper.

3. Capsicum grossum, the bell pepper. The fruit of this is red, and is the only kind proper for pickling, the skin being tender, whereas those of the other sorts are thin and tough.

CAP SQUARES, in gunnery, strong plates of iron which come over the trunnions of a gun, and keep it in the carriage.

CAPSTAN, or Main capstan, in a ship, a large piece of timber in the nature of a windlass, placed next behind the mainmast, its foot standing in a step on the lower deck, and its head between the upper decks, formed into several squares with holes in them. Its use is to weigh the anchors, to hoist up or strike down topmasts, to heave any weighty matter, or to strain any rope that requires a main force.

Capstan *Jear* is placed between the mainmast and the mizen, and serves to strain any rope, heave upon the jear rope or upon the viol, or hold off by at the weighing of an anchor.

CAPSULE, among botanists, a species of pericarpium or seed vessel.

Capsulæ atrabiliariæ, called also glandulæ renales, and renes succenturiati, are two yellowish glands of a compressed figure, lying on each side of the upper part of the kidneys. See Anatomy.

CAPTION, in law, is where a commission is executed, and the commissioners subscribe their names to a certificate, declaring when and where the commission was executed. It relates chiefly to commissions to take answers in chancery and depositions of witnesses, and take fines of lands, &c.

Caption and Horning, in the law of Scotland. When a decrete or sentence is obtained against any person, the obtainer takes out a writ, whereby the party decerned is charged to pay or fulfil the will of the decrete, under the pain of rebellion: this writ is called letters of horning. If he refuses to comply, then the writ or letters of caption may be raised, whereby all the inferior judges and magistrates are commanded to assist in apprehending the rebel, and putting him in prison.

CAPURA, a genus of the class and order hexandria monogynia. The essential character is, cal. none; cor. six cleft; stam. within the tube; germ. superior; stigma globular; per. berry. There is one species, a native of the East Indies.

CAPUT draconis. the Dragon's head, in astronomy, the ascending node of the moon. It is also a star of the first magnitude, in the head of the constellation Draco.

Caput mortuum, in chymistry, that thick dry matter, which remains after distillation of any thing, but of minerals especially. See Chymistry.

CARABINE, a fire arm, shorter than a musket, carrying a ball of twenty-four in the pound, borne by the light horse, hanging at a belt over the left shoulder.

CARABUS, in zoology, a genus of insects belonging to the order of coleoptera, or the beetle kind. The feelers are bristly; the breast is shaped like a heart, and marginated, and the elytra are likewise marginated. There are 34 species of this genus, mostly distinguished by their colour. The most remarkable is the crepitans, or bombardier, with the breast, head, and legs ferruginous, or iron coloured, and the elytra black. It keeps itself concealed among stones, and makes but little use of its wings; when it moves it is by a sort of jump; and whenever it is touched, it makes a noise resembling the discharge of a musket in miniature, during which a blue smoke may be perceived proceeding from it. The insect may be made to play off its artillery, by scratching its back with a needle. A bladder placed near the anus, is the arsenal whence it derives its store, and this is its chief defence against an enemy; but the smoke emitted seems altogether inoffensive, except by causing a fright, though it is useful to the insect by conceali g its course. Its chief enemy is another species of the same genus, but four times larger. When pursued and fatigued, the bombardier has recourse to stratagem, by lying down in the path of the large carabus, which advances with open mouth and claws to seize

it; but on the discharge of the artillery, suddenly draws back, and remains awhile confused, during which the bombardier conceals himself, in some crevice if there is one; but if not, the larger carabus renews the attack, takes his prisoner by the head and tears it off.

CARACOL, in architecture, denotes a staircase in a helix or spiral form.

CARACT, CARAT, or CARRAT, the name of that weight which expresses the degree of fineness that gold is of. The mint master, or custom, has fixed the purity of gold at 24 caracts; though it is not possible so to purify and refine that metal, but it will want still about one fourth part of a caract in absolute purity and perfection. The caract is divided into $\frac{1}{4}, \frac{1}{8}, \frac{1}{16}, \frac{1}{32}$. These degrees serve to distinguish the greater or lesser quantity of alloy therein contained: for instance, gold of 22 caracts, is that which has two parts of silver, or of any other metal, and 22 of fine gold.

It is also a certain weight which goldsmiths and jewellers use with which to weigh precious stones and pearls. This caract weighs four grains, but something lighter than the grains of other weights. Each of these grains is subdivided into $\frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \frac{1}{16}$, &c.

CARAGROUTH, in commerce, a silver coin of the empire, weighing nine drachms. It goes at Constantinople for 120 aspers.

CARBON, or the radical of carbonic acid, has not, unless the diamond is admitted as such, been yet obtained in a separate state; charcoal, which was once so esteemed, appearing to be a compound substance. Nor is it ever found united with caloric, in a gaseous state, unaccompanied by some third principle. Its taste, smell, and colour are unknown. It is infusible and indissoluble by caloric, and is hence esteemed the most refractory substance in nature. It has no evident attraction for nitrogen alone, but combines with it by the intervention of other principles. With hydrogen it has a strong affinity, uniting and forming a gas termed carbonated hydrogen; hydrogen gas having the power of holding it in solution.

The diamond, which exceeds all other gems in hardness, density and refraction of the rays of light, crystalizes in two tetrahedral and trihedral pyramids, united base to base, or in hexahedral prisms terminating in trihedral summits, or in irregular polyhedral grains. At a very high temperature it burns, becomes black and opaque, and is converted into gas. Sp. gr. about 3,5.

Newton conjectured the diamond to be a combustible body. Guyton, in 1785, inferred its similarity to charcoal, from its leaving an effervescent alkali, after combustion in fused nitre. Lavoisier found that on burning it in closed vessels, it yielded carbonic acid. This has also been proved by Mr. Tennant, who performed the combustion in a crucible of gold. Berthollet considered it as crystalized charcoal.

Since this, Guyton, having burnt the diamond in oxygen gas, by the solar rays, and thereby having obtained carbonic acid without residue, presumed that he had ascertained the diamond to be pure carbon, or the pure combustible matter of the carbonic genus, yielding the pure acidifiable basis of the carbonic acid. He found its combustion required a much higher temperature than charcoal; but this, he observes, takes place with other acidifiable bases, their first degrees of oxydation being difficultly produced, although their subsequent acidification is easy. It also required more oxygen for its complete combustion than charcoal; one part of diamond absorbing four of oxygen, and producing five of carbonic acid; this he remarks is not to be wondered at, since, being pure carbon, it contains none of the oxygen principle, and therefore demands more. In proportion therefore as substances contain pure combustible matter, will, in fact, be the difficulty of their combustion, their first degrees of oxygenation proceeding so slowly. Thus he accounts for plumbago, or black lead, which is a carbonic combustible, richer in combustible matter than charcoal itself, not burning, but at a very high degree of temperature: and thus he accounts for the incombustibility of anthracolite, Kilkenny coal, the brilliant charcoal of certain vegetables, &c. The diamond is therefore to be considered as pure carbon; plumbago, carbon oxygenized in the first degree; charcoal, an oxyd of the second, obtained from various substances in the animal, vegetable, and mineral kingdoms, generally by volatilizing their other constituent parts. When obtained in a state of purity, it resists the strongest heat in closed vessels. It decomposes sulphuric acid from its affinity with oxygen exceeding that of sulphur. It decomposes nitric acid with great rapidity; and if the charcoal is first powdered, and the acid strong, and allowed to run down the side of the vessel, to mix with the charcoal, it burns with rapidity, with a beautiful flame, throwing up the powder so as to resemble a beautiful fire work. With nitrate of potash, it detonates in a hot crucible, leaving a fixed alkali behind. It is dissolved by the alkalies, and by the sulphurets of alkali, both in the dry and moist way. It does not unite with metals, but restores their oxyds to a metallic state.

Charcoal possesses the power of absorbing several gases, which thus condensed retain their properties, and even exert them in some instances more powerfully. It decomposes water at the common temperature, carbonic acid and carbonated hydrogen being separated. If burnt in contact with common air, its acidifiable base attracts oxygen, and this peculiar acid is formed, which, with a certain proportion of caloric, assumes a gaseous form. If burnt in oxygen gas, its peculiar acid is plentifully formed, the charcoal burning with considerably increased rapidity, and if the lighter charcoal made from bark is used, a very brilliant effect is produced from the numerous vivid coruscating sparks.

CARBONATES, are neutral salts, composed of the carbonic acid, and certain bases: thus carbonate of ammonia, or mild volatile alkali, consists of carbonic acid and pure or caustic ammonia. Owing to the weakness of this acid, the characters of their bases are generally most predominant.

The carbonates are not acted on by light, oxygen, or nitrogen; nor do they deliquesce with the moisture of the atmosphere. Although charcoal decomposes the phosphoric acid alone, the carbonates are decomposed by phosphorus; this difference arises from the attraction which the phosphoric acid exercises on the base of the carbonate; from similar causes, the effects of different combustible bodies on them vary much. All the other acids have a greater attraction for the earthy and alkaline bases than the carbonic; that acid being disengaged from the carbonates by their addition. So feeble is this acid, that it is separated from most of its bases by heat only.

CARBUNCLE, in natural history, a very elegant gem, the colour of which is deep red with an admixture of scarlet. See GARNET.

CARBUNCLE, or ANTHRAX, in surgery, an inflammation which arises, with a vesicle or blister, almost like those produced by burning. This inflammation, for the most part, terminates in a sphacelus, and putrifies the subjacent parts down to the bone, they becoming as black as a coal. A carbuncle always breaks out very speedily, even in the space of an hour or two, attended with heat and pain: as soon as it is opened, it discharges a livid sanies, or sometimes a limpid water: it is black within, which is a sign that the sphacelus has seized the subjacent parts, and is making its progress: but the putrid flesh in those who recover, suppurates, and parts from the sound. The size of these pestilential blisters is various, more or less; as is also their number in the patient; for there is no part of the body which they do not infest, and they generally appear in company with buboes.

Those carbuncles which arise in the face, neck, breast, or armpits, are observed to be of the worst kind, for they generally kill the patient.

In the external treatment, some of the modern physicians use only scarification in this case, with very good success; others open the eruptions with a pair of scissars, and having discharged the matter, frequently wash the carbuncle with sp. vin. camph. or sp. vin. in which has been digested a little theriaca: they afterward apply a maturating cataplasm, which is to be continued till the carbuncle separates from the sound parts; then they cut it out all at once.

CARBUNCLE, in heraldry, a charge or bearing consisting of eight radii, four whereof make a common cross, and the other four a saltier.

CARCASS, a composition of combustibles. Carcasses are of two sorts, oblong and round: the uncertain weight of the first sort has almost rendered them useless. They are prepared in the following manner: Boil 12 or 15lb. of pitch in a glazed earthen pot; mix with that 3lb. of tallow, 30lb. of powder, 6lb. of saltpetre, and as many stopins as can be put in. Before the composition is cold, the carcass must be filled; to do which, smear your hands with oil or tallow, and fill the carcass one third full with the above composition; then put in loaded pieces of gun or pistol barrels, loaded grenades, and fill the intervals with composition; cover the whole over with coarse cloth, well sewed together, keeping it in a round form. Then put it into the carcass, having a hollow top and bottom, with bars running between them to hold them together, and composed of four slips of iron jointed at top, and fixed at the bottom, at equal distances, to a piece of iron, which, together with the hoops, when filled, form a complete globular body. When quite finished and cold, the carcass must be steeped in melted pitch, and then instantly immerged in cold water. Lastly, bore three or four holes at top, and fill the same with fuse composition, covering the holes with pitch until used. Carcasses are thrown out of mortars, and weigh from 50 to 230lb. according to the size of the mortars they are to be thrown out of. There are other carcasses for the sea service, which differ from a shell only in the composition, and in the four holes from which they burn when fired.

CARCASSES were first used by the bishop of Munster, at the siege of Groll in 1672, where the duke of Luxemburg commanded.

CARCERES, in the ancient circensian games, were enclosures in the circus, in which the horses were restrained till the signal was given for starting, when, by an admirable contrivance, they all at once flew open.

CARD, among artificers, an instrument consisting of a block of wood, beset with sharp teeth, serving to arrange the hairs of wool, flax, hemp, and the like: there are different kinds of them, as hand cards, stock cards, &c.

CARDS, among gamesters, little pieces of fine thin pasteboard of an oblong figure, of several sizes, but most commonly in England $3\frac{1}{2}$ inches long, and $2\frac{1}{2}$ broad, on which are painted several points and figures. The moulds and blocks for making cards, are exactly like those that were used for the first books: they lay a sheet of wet or moist paper on the block, which is first slightly done over with a sort of ink made with lampblack diluted in water, and mixed with some starch to give it a body. They afterward rub it off with a round list. The court cards are coloured by means of several patterns stiled stane files. These consist of papers cut through with a penknife, and in these apertures, they apply severally the various colours, as red, black, &c. These patterns are painted with oil colours, that the brushes may not wear them out; and when the pattern is laid on the pasteboard, they slightly pass over it a brushful of colour, which, leaving it within the openings, forms the face or figure of the card.

CARDAMINE, lady's smock; a genus of the siliquosa order, in the tetradynamia class of plants; and in the natural method ranking under the 39th order, siliquosa. The siliqua parts asunder with a spring, and the valves roll spirally backward; the stigma is entire, and the calyx a little gaping. Of this there are 18 species; but the most remarkable is the

Cardamine pratensis, with a large purplish flower. It grows naturally in many parts of Britain, and is also called cuckow flower. There are four varieties, *viz.* the single, with purple and white flowers, which are frequently intermixed in the meadows; and the double of both colours. The single sorts are not admitted into gardens; but the double deserve a place, as making a pretty appearance during the time they are in flower.

CARDAMOM. See AMOMUM and MATERIA MEDICA.

CARDIA, or CARDIUM, in natural history, a genus of the vermes testaceæ, or shell fish, the shell of which is formed of two ovals, and resembles the figure of a heart at cards: the valves are equal and gibbose.

Of this genus there are 21 species, some nearly globose, others of a triangular figure, and others irregularly oblong. Under this genus are comprehended the cockles, ark shells, &c. together with the pectini inauriti, or scallops without ears, as they are called.

CARDIAC, an appellation given to such medicines as preserve or increase the strength of the heart, and by that means the vital forces, though they do not immediately operate upon the heart, nor are particularly appropriated to the corroboration of that part. See MATERIA MEDICA.

CARDIALGIA, the heartburn, in medicine, a disorder of the stomach attended with anxiety, a nausea, and often a reaching or actual vomiting. See MEDICINE.

CARDINAL, an ecclesiastical prince in the Romish church, being one who has a voice in the conclave at the

election of a pope. The cardinals were originally nothing more than deacons, to whom was intrusted the care of distributing the alms to the poor of the several quarters of Rome; and as they held assemblies of the poor in certain churches of their several districts, they took the title of these churches. They began to be called cardinals in the year 300, during the pontificate of St. Sylvester, by which appellation were meant the chief priests of a parish, and next in dignity to a bishop. This office grew more considerable afterward, and by small degrees arrived at its present state.

The cardinals compose the pope's council, and till the time of Urban VIII. were styled most illustrious; but by a decree of that pope in 1630, they had the title of eminence conferred upon them. At the creation of a new cardinal, the pope performs the ceremony of shutting and opening his mouth, which is done in a private consistory. The shutting his mouth, implies the depriving him of the liberty of giving his opinion in congregations; and the opening his mouth, which is performed fifteen days after, signifies the taking off this restraint. However, if the pope happens to die during the time a cardinal's mouth is shut, he can neither give his voice in the election of a new pope, nor be himself advanced to that dignity.

The cardinals are divided into six classes or orders, consisting of six bishops, fifty priests, and fourteen deacons, making in all seventy; which constitute the sacred college. The number of cardinal bishops has very seldom been changed, but that of priests and deacons has varied at different times. The privileges of the cardinals are very great; they have an absolute power in the church during the vacancy of the holy see: they have a right to elect the new pope, and are the only persons on whom the choice can fall: most of the grand offices in the court of Rome, are filled by cardinals. The dress of a cardinal is a red soutanne, a rochet, a short purple mantle, and the red hat. When they are sent to the courts of princes, it is in quality of legates a latere; and when they are appointed governors of towns, their government is called by the name of legation.

CARDIOID, in the higher geometry, an algebraical curve, so called from its resemblance to a heart.

The Cardioid is thus generated. APB, Plate XIV. Miscell. fig. 11. is a circle and A B its diameter. Through one extremity A of the diameter draw a number of lines A P Q, cutting the circle in P; upon these set off always P Q equal to the diameter A B; so shall the points Q be always in the curve of the cardioid.

From this generation of the curve, its chief properties are evident, *viz.* that,

every where PQ = AB,

CQ, or QQ is = A*a* or 2 AB,

AQ = AB ± AP.

P always bisects QQ.

The cardioid is an algebraical curve, and the equation expressing its nature is thus:

Put *a* = AB the diameter,

z = *a*D perp. AB,

y = DQ perp. AD; then is

$$\left.\begin{array}{l} y^4 - 6ay^3 + 2z^2y^2 - 6az^2y + z^4 \\ \quad + 12a^2y^2 - 8a^3y + 3a^2z^2 \end{array}\right\} = 0,$$ which is the equation of the curve.

Many properties of the cardioid may be seen in the Philosophical Transactions, 1741.

CARDIOSPERMUM, heart pea, a genus of the trigynia order, in the octandria class of plants, and in the natural method ranking under the 39th order, trihilatæ. The calyx is tetraphyllous; the petals four; the nectarium tetraphyllous and unequal; the capsules three, grown together, and inflated. There are three species, natives of the East and West Indies.

CARDUUS, the thistle, a genus of the polygamia æqualis order, in the syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The calyx is ovate, imbricated with prickly scales, and the receptacle hairy. Of this genus there are 51 species, ten of which are natives of Britain; and being troublesome weeds, they require no description. Some of the exotics are propagated in gardens for the sake of variety.

CARDUUS *benedictus*. See CENTAURIA and MATERIA MEDICA.

CAREENING, in the sea language, the bringing a ship to lie down on one side, in order to trim and caulk the other side. A ship is said to be brought to the careen when the most of her lading being taken out, she is hauled down on one side by a small vessel as low as necessary; and there kept by the weight of the ballast, ordnance, &c. as well as by ropes, lest her masts should be strained too much; in order that her sides and bottom may be trimmed, seams caulked, or any thing that is faulty under water mended. Hence when a ship lies on one side when she sails, she is said to sail on the careen.

CAREX, the sedge, a genus of the monoecia triandria class and order of plants, and in the natural method ranking under the 3d order, calamariæ. The characters are: the male flowers are digested into a long spike; the calyx is an oblong and imbricated amentum, consisting of acute, hollow, and lanceolated scales, each containing one flower: there is no corolla; the stamina are three erect setaceous filaments of the length of the calyx; the antheræ are oblong and erect. In the female flowers the calyx is the same as in the male; there are no petals, but there is an inflated oblong nectarium; the germen is triangular, and is placed within the nectarium; the style is very short; the stigmata are two or three; long, crooked, pointed, and hoary. The nectarium grows larger when the flower is fallen, and contains the seed; which is single, of an acute ovated form, triangular, and has one of its angles usually much smaller than the others. There are 97 species. The common sedge may serve as an example for all.

CARICA, the papaw, a genus of the decandria order, belonging to the dioecia class of plants, and in the natural method ranking under the 38th order, tricoccæ. The calyx of the male, almost none; the corolla is quinquefid and funnel shaped; the filaments in the tube of the corolla a longer and a shorter one alternately. The calyx of the female quinquedentated; the corolla is pentapetalous, with five stigmata; the fruit an unilocular and polyspermous berry.

1. Carica papaya rises with a thick, soft, herbaceous stem, to the height of 18 or 20 feet, naked till within two or three feet of the top. The leaves come out on every side, upon very long footstalks; in full grown plants they are very large, and divided into many lobes deeply sinu-

ated. The flowers of the male plant are of a pure white, and have an agreeable odour. The flowers of the female papaya are large, bell shaped, composed of six petals, and commonly yellow; when these fall away, the germen swells to a fleshy fruit, of the size of a small melon. These fruits are of different forms: some angular, and compressed at both ends; others oval or globular, and some pyramidal. The fruit, and all the other parts of the tree, abound with a milky acrid juice, which is applied for killing of ringworms. When the roundish fruit are nearly ripe, the inhabitants of India boil and eat them with their meat as we do turnips. They have somewhat the flavour of a pompion. But they mostly pickle the long fruit, and thus they maké no bad succedaneum for mango. The buds of the female flowers are gathered, and made into a sweetmeat; and the inhabitants are such good managers of the produce of the tree, that they boil the shells of the ripe fruit into a repast, and the insides are eaten with sugar and pepper, like melons. The stem being hollow, has given birth to a proverb in the West India islands, where, in speaking of a dissembling person, they say he is as hollow as a papaw.

2. Carica prosoposa, differs from the other in having a branching stalk, the lobes of the leaves entire, the flower of a rose colour, and the fruit shaped like a pear, and of a sweeter flavour than the papaya. Both species being natives of hot countries, they cannot be preserved in Britain unless constantly kept in a warm stove. They are easily propagated by seeds, which are annually brought in plenty from the West Indies, though the seeds of the European plants ripen well.

CARINA, in architecture, a name given by the Romans to all buildings in the form of a ship, from *carina*, the keel of a ship: as we still apply the word *nave* from *navis*, a ship, to the middle or principal vault of our churches, because it has that figure.

CARINA, in anatomy, a term used for the fibrous rudiments, or embryo of a chick, appearing in an incubated egg.

The carina consists of the entire vertebræ, as they appear after ten or twelve days incubation.

CARISSA, in botany, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 30th order, contortæ. It has two berries, many seeded. There are two species, trees of Africa.

CARLINA, the carline thistle, a genus of the polygamia æqualis order, in the syngenesia class of plants; and in the natural method ranking under the 49th order, compositæ. The calyx is radiated with long coloured marginal scales. There are nine species; but the carlina vulgaris is the only one that is a native of Britain. All the others are natives of the south of France or Italy, and are very easily propagated in this country by seeds. The roots are used in medicine, and for that purpose are imported. As we receive them they are about an inch thick, externally of a rusty brown colour, corroded as it were on the surface, and perforated with numerous small holes, appearing as if worm eaten. They have a strong smell, and a subacrid, bitterish, weakly aromatic taste. They are reckoned warm alexipharmics and diaphoretics.

CARLINE, or CAROLINE, a silver coin current in the Neapolitan dominions, and worth about fourpence of our money.

CARLINGS, or CARLINES, in a ship, two pieces of timber lying fore and aft, along from beam to beam, whereon the ledges rest on which the planks of the ship are fastened.

CARLOCK, in commerce, a sort of isinglass made with the sturgeon's bladder, imported from Archangel. The chief use of it is for clarifying wine; but it is also used by dyers.

CARMELITES, or WHITE FRIARS, are an order of Our Lady of mount Carmel, making one of the four orders of mendicants. They pretend to derive their origin from the prophets Elijah and Elisha. Their original rules contained sixteen articles, one of which confined them to their cells, and enjoined them to employ themselves day and night in prayer; another prohibited the brethren having any property; another enjoined fasting, from the feast of the exaltation of the holy cross till Easter, excepting on Sundays; abstinence at all times from flesh was enjoined by another article: one obliged them to manual labour; another imposed a strict silence on them from vespers till the tierce the next day. However, these constitutions have been in some respects altered.

CARMINATIVES, in pharmacy, medicines used in colics, or other flatulent disorders, to dispel the wind. See MATERIA MEDICA.

CARMINE, a powder of a very beautiful red colour, bordering upon purple, and used by painters in miniature, though but rarely because of its great price. The mode of preparing this colour is kept from the public. The receipts which have been from time to time published concerning the preparation of this and other colours, have been rarely found to succeed in practice. It is said to be extracted from cochineal by means of water, wherein chouan and antour have been infused; some add rocou, but this gives it too much of the opal cast. Others make carmine with Brazil wood, fernambouc, and leaf gold, beaten in a mortar, and steeped in white wine vinegar; the scum arising from this mixture, upon boiling, when dried, makes carmine; but this kind is vastly inferior to the former. There is another carmine, made of Brazil wood and fernambouc, by a different preparation.

CARNEDDE, in British antiquity, denotes heaps of stones supposed to be druidical remains, and thrown together on some important occasions. They are very common in the isle of Anglesey, and were also used as sepulchral monuments, in the manner of tumuli. Hence it is inferred, that the ancient Britons had the custom of throwing stones on the deceased. From this custom is derived the Welsh proverb, *karn ardyben;* "Ill betide thee."

CARNEL, among ship carpenters. The building of ships, first with their timbers and beams, and after bringing on their planks, is called carnel work, to distinguish it from clinch work.

CARNELIAN, *sarda*, in natural history, a precious stone, of which there are three kinds, distinguished by three colours, a red, a yellow, and a white. Authors have attributed medicinal virtues to this stone, meaning the red carnelian; this, therefore, is to be understood as the sarda, or carnelian of the shops. It is very well known among us; and is found in roundish or oval masses, much like our common pebbles; and is generally met with between an inch and two or three inches in diameter.

It is of a fine, compact, and close texture, of a glossy surface; and in the several specimens is of all the degrees of red, from the palest flesh colour to the deepest blood red. It is generally free from spots, clouds, or variegations: but sometimes it is veined very beautifully with an extremely pale red, or with white; the veins forming concentric circles, or other less regular figures, about a nucleus, in the manner of those of agates. The pieces of carnelian which are all of one colour, and perfectly free from veins, are those which our jewellers generally make use of for seals, though the variegated ones are much more beautiful. The carnelian is tolerably hard, and capable of a very good polish: it is not at all affected by acid menstruums; the fire divests it of a part of its colour, and leaves it of a pale red; and a strong and long continued heat will reduce it to a pale dirty gray. The finest carnelians are those of the East Indies; but there are very beautiful ones found in the rivers of Silesia and Bohemia; and we have some not despicable in England.

Though the ancients have recommended the carnelian as an astringent, and attributed a number of fanciful virtues to it, we know no other use of the stone than the cutting seals on it, to which purpose it is excellently adapted, as being not too hard for cutting, and yet hard enough not to be liable to accidents, to take a good polish, and to separate easily from the wax.

According to the new arrangement in natural history, the carnelian is a variety of the chalcedony of færo, and is composed of 84 parts of silica, and 16 of alumine, mixed with iron. The name has been given to different hard stones, capable of a fine polish, but chalcedony forms the basis of the greater number. The varieties in their colours, transparency, &c. have given occasion to their being known under a great variety of names.

CARNIVAL, or Carnaval, a time of rejoicing, a season of mirth, observed with great solemnity by the Italians, particularly at Venice, lasting from Twelfth day till Lent. Feasts, balls, operas, concerts of music, intrigues, marriages, &c. are chiefly held in carnival time. The carnival begins at Venice the second holiday in Christmas; then it is they begin to wear masks, and open their playhouses and gaming houses; the Place of St. Mark is filled with mountebanks, pedlars, and such like mob, who flock thither from all parts. There have been no less than seven sovereign princes, and thirty thousand foreigners here, to partake of these diversions.

CARNIVOROUS, an appellation given to animals which naturally feed on flesh, and thence called beasts or birds of prey. Some will have it, that no quadrupeds are naturally carnivorous but those furnished with canine or dog teeth: on which principle mankind are excluded out of the number of naturally carnivorous animals; and, in fact, animal food must undergo various preparations before it is fit for the use of man.

CAROLINE BOOKS, the name of four books, composed by order of Charlemagne, to refute the second council of Nice. These books are couched in very harsh and severe terms, containing one hundred and twenty heads of accusation against the council of Nice, and condemning the worship of images.

CAROLINEA, a genus of the monadelphia polyandria class and order. The essential character is; monogyneous. calyx simple, tubular, truncate; petal ensiform; pome five grooved, two celled. There are two species, natives of Guiana and Tobago.

CAROLOSTADIANS, in church history, an ancient branch of Lutherans, who denied the real presence in the eucharist.

CAROLUS, an ancient English broad piece of gold, struck under Charles I. Its value has of late been at twenty-three shillings sterling, though at the time it was coined, it is said to have been rated at twenty shillings.

Carolus, a small copper coin, with a little silver mixed with it, struck under Charles VIII. of France. The carolus was worth twelve deniers when it ceased to be current.

CAROTEEL, in commerce, an uncertain weight or quantity of goods. Thus a caroteel of cloves is from four to five hundred weight, of currants from five to nine, of mace about three hundred, of nutmegs from six to seven hundred and a half.

CAROTIDS, in anatomy, two arteries of the neck, which convey the blood from the aorta to the brain. See Anatomy.

CAROXYLON, a genus of the pentandria monogynia class and order: the essential character is; corolla five petaled; nect. five leaved, converging, inserted into the corolla; seed clothed. There is one species.

CARPESIUM, a genus of the syngenesia polygamia superflua class and order: the essential character is; calyx imbricate; down none; recept. naked. There are two species.

CARP. See Cyprinus.

CARPÆA, a kind of dance anciently practised in Athens and other Grecian states, by two persons, the one acting as a labourer, the other as a robber. The labourer, laying by his arms, goes to ploughing and sowing: the robber appears, and the other betakes himself to his arms, and fights in defence of his oxen. The whole was performed to the sound of flutes. Sometimes the one was victor and sometimes the other, and the reward was the oxen and plough. The great object of this national exercise was to teach and accustom the peasants to defend themselves against the attacks of ruffians.

CARPET, a sort of stuff wrought with the needle or on a loom, which is part of the furniture of a house, and commonly spread over tables, or laid upon the floor. Persian and Turkey carpets are most esteemed; though at Paris there is a manufactory after the manner of Persia, where they make them little inferior, not to say finer, than the true Persian carpets. They are velvety, and perfectly imitate the carpets which come from the Levant. There are also carpets of Germany, some of which are made of woollen stuffs, as serges, &c. and called square carpets; others are made of wool also, but wrought with the needle, and pretty often embellished with silk; and lastly there are carpets made of dog's hair. We have likewise carpets made in England, which are used either as floor carpets, or to make chairs and other household furniture.

In weaving carpets the design or pattern is traced in its proper colours on cartons, tied before the workman, who looks at them every moment, because every stitch is marked upon them, as it is to be in his work. By this means he always knows what colours and shades he is to

use, and how many stitches of the same colour. In this he is assisted by squares, into which the whole design is divided; each square is subdivided into ten vertical lines, corresponding with the parcels of ten threads of the warp; and besides, each square is ruled with ten horizontal lines, crossing the vertical lines at right angles. The workman, having placed his spindles of thread near him, begins to work on the first horizontal line of one of the squares.

The lines marked on the carton are not traced on the warp, because an iron wire, which is longer than the width of a parcel of ten threads, supplies the place of a cross line. This wire is managed by a crook at one end, at the workman's right hand; toward the other end it is flatted into a sort of knife, with a back and edge, and grows wider to the point. The weaver fixes his iron wire horizontally on the warp, by twisting some turns of a suitable thread of the woof round it, which he passes forward and backward, behind a fore thread of the warp, and then behind the opposite thread, drawing them in their turn by their leishes. Afterward he brings the woof thread round the wire, in order to begin again to thrust it into the warp. He continues in this manner to cover the iron rod or wire, and to fill up a line to the tenth thread of the warp. He is at liberty either to stop here or to go on with the same cross line in the next division, according as he passes the thread of the woof round the iron wire, and into the warp, the threads of which he causes to cross one another at every instant: when he comes to the end of the line, he takes care to strike in or close again all the stitches with an iron reed, the teeth of which freely enter between the empty threads of the warp, and which is heavy enough to strike in the woof he has used. This row of stitches is again closed and levelled, and in the same manner the weaver proceeds; then with his left hand he lays a strong pair of sheers along the finished line, cuts off the loose hairs, and thus forms a row of tufts perfectly even, which, together with those before and after it, form the shag. Thus the workman follows stitch for stitch, and colour for colour, the plan of his pattern, which he is attempting to imitate; and he paints magnificently, without having the least notion of painting or drawing.

CARPINUS, the hornbeam, a genus of the polyandria order, in the monoecia class of plants; and in the natural method ranking under the 50th order, amentaceæ. The calyx of the male is monophyllous and ciliated; there is no corolla, but 20 stamina. The calyx of the female is monophyllous and ciliated; no corolla; two germens, with two styles on each. The fruit is an egg shaped nut. There are four species, *viz.*

1. Carpinus betulus, or common hornbeam; a deciduous tree, native of Europe and America. Its leaves are of a darkish green, and about the size of those of the beech, but more pointed and deeply serrated. Its branches are long, flexible, and crooked; yet in their general appearance resemble those of the beech. Indeed there is so great a likeness between these two trees, especially in their shrubby and underwood state, that it would be difficult to distinguish them, were it not for the glossy varnish with which the leaves of the beech are strongly marked. As an underwood, it affords stakes and edders, fuel and charcoal. Its timber ranks with that of the beech and the sycamore; and the inner bark is said to be much used in Scandinavia to dye yellow.

2. Carpinus ostrya, the hop hornbeam, a native of Italy and Virginia.

3. Carpinus Virginiana, or flowering hornbeam.

4. Carpinus duinensis.

CARPOCRATIANS, heretics, who sprung up toward the middle of the second century, being a branch of the ancient Gnostics. They are said to have held a community of wives, and maintained that a man cannot arrive at perfection without having passed through all criminal actions; laying down as a maxim, that there is no action bad in itself, but only from the opinion of men.

CARPODETUS, a genus of the pentandria monogynia class and order: the essential character is, calyx five notched, corolla five petaled; stigma flat headed; berry globular, five celled. There is one species, a native of New Zealand.

CARPUS, the wrist. See ANATOMY.

CARRARA *marble*, among artificers, the name of a species of white marble, distinguished from the Parian called the statuary marble, by being harder and less bright.

CARRIER. Every person carrying goods for hire is deemed a carrier, and as such is liable in law for any loss or damage that may happen to them whilst in his custody. Waggoners, captains of ships, lightermen, &c. are therefore carriers; but a stage coachman is not within the custom as a carrier: neither are hackney coachmen carriers within the custom of the realm, so as to be chargeable for the loss of goods, unless they are expressly paid for that purpose, for their undertaking is only to carry the person.

If a person takes hire for carrying goods, although he be not a common carrier, he may nevertheless be charged upon a special assumpsit; for where hire is taken a promise is implied; and where goods are delivered to a carrier, and he is robbed of them, he shall be charged and answer for them on account of the hire, and the carrier can be no loser, as he may recover against the hundred. Goods sent by a carrier cannot be distrained for rent; and any person carrying goods for all persons indifferently, is to be deemed a common carrier as far as relates to this privilege. A delivery to a servant is a delivery to the master; and if goods are delivered to a carrier's porter and lost, an action will lie against the carrier. 1 Salk. 282.

Where a carrier gives notice by printed proposals that he will not be responsible for certain valuable goods if lost, if more than the value of a sum specified, unless entered and paid for as such; and valuable goods of that description are delivered to him, by a person who knows the conditions, but concealing the value, pays no more than the ordinary price of carriage and booking; the carrier is, under such circumstances, neither responsible to the sum specified, nor liable to repay the sum paid for carriage and booking. M. 30. Geo. III. 1. H. B. 298.

A carrier who undertakes for hire to carry goods, is bound to deliver them at all events, unless damaged and destroyed by the act of God, or the king's enemies; and if any accident, however inevitable, happen through the intervention of human means, a carrier becomes responsible. 1 T. R. 27.

CARRONADE, a short kind of ordnance, capable of carrying a large ball, and useful in close engagements at sea It has its name from Carron, the place where this kind of ordnance was first made.

CARROT, *daucus*, in botany. See Daucus.

CARRUCA, in antiquity, a splendid kind of car, or chariot, highly decorated with gold, silver, ivory, &c. in which the emperors, senators, and people of high rank, were carried. The word was used also in the middle ages to signify a plough. Hence

CARRUCAGE denoted the ploughing of ground: either ordinary, as for grain, hemp, flax; or extraordinary, as for wood, dyers' weed, rape, and the like: and

CARRUCATE, in our ancient history, denotes as much arable land as can be tilled in one year with one plough. In the Doomsday inquisition, the arable land is estimated in carrucates, the pasture in hides, and the meadow land in acres. In the reign of Richard I. the carrucate was estimated at 60 acres; in the time of Edward I. at 180, and in the 23d of Edward III. it contained 112 acres.

CARTHAMUS, a genus of the order of polygamia æqualis, in the syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The calyx is ovate, imbricated with scales, close below, and augmented with subovate foliaceous appendices at top. Of this genus there are 10 species; but the only remarkable one is

Carthamus tinctorius, with a saffron coloured flower, a native of Egypt and some of the warm parts of Asia. It is cultivated in many parts of Europe, and in the Levant, whence great quantities of it are annually imported into Britain for dyeing and painting. It is an annual plant, and rises with a stiff ligneous stalk, about $2\frac{1}{2}$ or 3 feet in height, dividing upward into many branches, with oval pointed leaves sitting close to the branches. The flowers grow single at the extremity of each branch; the heads of the flowers are large, of a fine saffron colour, and are the part used for the purposes above mentioned.

CARTHUSIANS, a religious order, founded in the year 1080, by one Bruno. Their rules are very severe. They are not to go out of their cells, except to church, without leave of their superior, nor speak to any person without leave. They must not keep any portion of their meat or drink till next day; their beds are of straw, covered with a felt; their clothing two hair cloths, two cowls, two pair of hose, and a cloak, all coarse. In the refectory they are to keep their eyes on the dish, their hands on the table, their attention on the reader, and their hearts fixed on God. Women are not allowed to come into their churches.

CARTILAGE, in anatomy, a body approaching much to the nature of bones, but lubricous, flexible, and elastic. See Anatomy.

CARTILAGINOUS *fishes*, or those with cartilaginous fins, constitute a class or order of fishes, called by Linnæus amphibia nantes. The term is applied to all those fish, the muscles of which are supported by cartilages, or gristles, instead of bones. They unite in their formation several leading properties of the other tribes. Like the cetaceous, they have lungs; and, like the spinous, they have gills, and a heart without a partition. Thus they possess a twofold manner of breathing; sometimes by their lungs, and sometimes by their gills. This double capacity of breathing in cartilaginous fish is one of the most remarkable features in the history of nature, as they are thus enabled to unite all the advantages of which their situation is capable, and draw from both elements every aid to their necessities or their enjoyment. The apertures by which they breathe are variously placed. The gills are affixed to these apertures, but without any bone to open and shut them. From the gills are cylindrical ducts running to the lungs, and which are supposed to convey the air that gives play to the organs. This tribe can live longer out of the water than those whose gills are more simple; they can venture their heads above the deep, and continue for hours out of their native element. This order includes the shark, lamprey, sturgeon, ray, &c.

CARTON, or Cartoon, in painting, a design drawn on strong paper to be afterward calked through, and transferred on the fresh plaster of a wall to be painted in fresco. Carton is also used for a design coloured for working in mosaic, tapestry, &c. The cartons at Hampton court are designs of Raphael Urbino. They are seven in number, and form only a small part of the sacred historical designs executed by this artist, while engaged in the chambers of the Vatican, under the auspices of popes Julius II. and Leo X. When finished they were sent to Flanders to be copied in tapestry, for adorning the pontifical apartments; the work was not, however, sent to Rome till after the death of Raphael. The cartons themselves lay long neglected after the sacking of Rome in the time of Clement VII. they were at length discovered and purchased by Rubens for Charles I. of England. They are held in the highest estimation by all those who have any pretensions to true taste, for their various and matchless merit, particularly with regard to the invention, and to the great and noble expression of such a variety of characters, countenances, and attitudes, as they are differently affected and properly engaged.

CARTOUCHE, in architecture and sculpture, an ornament representing a scroll of paper. It is usually a flat member, with wavings, to represent some inscription, device, cypher, or ornament of armoury. They are in architecture much the same as modillions; only these are set under the cornice in wainscoting, and those under the cornice at the eaves of a house.

Cartouche, in the military art, a case of wood, about three inches thick at the bottom, girt with marlin, holding about 400 musket balls, besides six or eight balls of iron, of a pound weight, to be fired out of a hobit, for the defence of a pass, &c. A cartouche is sometimes made of a globular form, and filled with a ball of a pound weight; and sometimes it is made for the guns, being of ball of half or quarter pound weight, according to the nature of the gun, tied in form of a bunch of grapes, on a tompion of wood, and coated over. These were made in the room of partridge shot.

CARTRIDGE, in the military art, a case of pasteboard or parchment, holding the exact charge of a fire arm. Those for muskets, carabines, and pistols, hold both the powder and ball for the charge; and those of cannon and mortars are usually in cases of pasteboard or tin, sometimes of wood, half a foot long, adapted to the caliber of the piece.

CARTS. Every cart, &c. for the carriage of any thing to and from any place where the streets are paved, within the bills of mortality, shall contain six inches in the felly; and no person shall drive any cart, &c. within the limits aforesaid, unless the name of the owner and number of

such cart be placed in some conspicuous part thereof, and his name entered with the commissioners of the hackney coaches, under the penalty of 40*s*. and any person may seize and detain such cart till the penalty be paid. 18. Geo. II. c. 33. And if the driver shall ride upon such cart without having a person on foot to guide it, he shall forfeit 10*s*. and the owner so guilty forfeits 20*s*. On changing property the name of the new owners shall be affixed, and entry shall be made with the commissioners of the hackney coaches. The entry of all carts driven within five miles of Temple bar, is strictly enjoined by the 24 Geo. III. s. 2. c. 27.

CARUM, a genus of the digynia order, in the pentandria class of plants, and in the natural method ranking under the 45th order, umbellatæ. The fruit is ovate, oblong, and striated; the involucrum monophyllous; the petals are carinated or keel shaped below, and emarginated by their inflection. There is one species,

Carum carni, the caraway of the shops, grows naturally in many places of Britain. It is a biennial plant, which rises from seeds one year, flowers the next, and perishes soon after the seeds are ripe. It has a strong aromatic taste, and a taper root like a parsnep, but much smaller, which runs deep into the ground, sending out many small fibres. From the root arises one or two smooth, solid, channelled stalks, about two feet high, with winged leaves, having long naked footstalks. The seed of this plant is one of the greater hot seeds, stomachic, carminative, and good in the colic. The officinal preparations of it are the seeds candied with sugar, and an oil distilled from the seed.

CARUNCULA. See Anatomy.

CARUNCLES in the urethra. See Surgery.

CARUS, in medicine, a sudden deprivation of sense and motion, affecting the whole body. See Medicine.

CARYATIDES, or Cariates, in architecture, a kind or order of columns or pilasters under the figure of women dressed in long robes, after the manner of the Carian people, and serving instead of columns to support the entablement.

CARYOCAR, in botany, a genus of the tetragynia order, in the polyandria class of plants. The calyx is quinquepartite, the petals five, the styles most frequently four. The fruit is a drupe, with nucleuses, and four furrows netted. There is one species.

CARYOPHYLLUS, the clove tree, a genus of the monogynia order, in the polyandria class of plants; and in the natural method ranking under the 19th order, hesperideæ. The corolla is tetrapetalous; the calyx tetraphyllous; the berry monospermous, below the receptacle of the flower. Of this there is but one species, *viz.*

Caryophyllus aromaticus, which is a native of the Molucca islands, particularly of Amboyna, where it is principally cultivated. The clove tree resembles in its bark the olive; and is about the height of the laurel. No verdure is ever seen under it. It has a great number of branches, at the extremities of which are produced vast quantities of flowers, that are first white, then green, and at last pretty red and hard. When they arrive at this degree of maturity, they are, properly speaking, cloves. As they dry, they assume a dark yellowish cast, and when gathered become of a deep brown. The season for gathering the cloves is from October to February. The boughs of the trees are then strongly shaken, or the cloves beaten down with long reeds. Large cloths are spread to receive them, and they are afterward either dried in the sun or in the smoke of the bamboo cane. The cloves which escape the notice of those who gather them, or are purposely left upon the tree, continue to grow till they are about an inch in thickness; and these falling off, produce new plants, which do not bear in less than eight or nine years. Those which are called mother cloves are inferior to the common sort, but are preserved in sugar by the Dutch, and in long voyages eaten after their meals, to promote digestion. The clove, to be in perfection, must be full sized, heavy, oily, and easily broken, of a fine smell, and of a hot aromatic taste, so as almost to burn the throat. It should make the fingers smart when handled, and leave an oily moisture upon them when pressed. In the East Indies, and in some parts of Europe, it is so much admired as to be thought an indispensable ingredient in almost every dish. Cloves are very hot, stimulating, aromatics; and possess in an eminent degree the general virtues of substances of this class. Their pungency resides in their resin, or rather in a combination of resin with essential oil; for the spirituous extract is very pungent: but if the oil and the resin contained in this extract are separated from each other by distillation, the oil will be very mild; and any pungency which it does retain, proceeds from some small portion of adhering resin, and the remaining oil will be insipid. No plant, or part of any plant, contains such a quantity of oil as cloves do. From 16 ounces Newman obtained by distillation two ounces and two drams, and Hoffman obtained an ounce and a half of oil from two ounces of the spice. The oil is specifically heavier than water. Cloves acquire weight by imbibing water; and this they will do at some considerable distance. The Dutch, who trade in cloves, make a considerable advantage by knowing this secret. They sell them always by weight; and when a bag of cloves is ordered, they hang it for several hours before it is sent in, over a vessel of water, at about two feet distance from the surface. This will add many pounds to the weight, which the unwary purchaser pays for on the spot. This is sometimes practised in Europe, as well as in the spice islands: but the degree of moisture must be more carefully watched in the latter; for there a bag of cloves will, in one night's time, attract so much water, that it may be pressed out by squeezing them with the hand. At Amboyna the company have allotted the inhabitants 4000 parcels of land, on each of which they were at first allowed, and about the year 1720 compelled, to plant about 125 trees, amounting in all to 500,000. Each of these trees produces annually on an average more than two pounds of cloves, and consequently the collective produce must weigh more than a million. See Plate XXVII. Nat. Hist. fig. 92.

CARYOTA, in botany, a genus of the monoecia polyandria plants, classed by Linnæus under palmæ: the male and female flowers of which are produced in separate parts of the same spadix; the corolla is divided into three hollow, lanceolated segments; the stamina are numerous filaments, longer than the corolla; the antheræ are linear; the corolla in the female flower is divided into two very small acuminated segments; the fruit is a round berry, containing a single cell; the seeds are two, large, oblong, rounded on one side, and flatted on the other. There are two species.

CASE, among grammarians, implies the different inflexions or terminations of nouns, serving to express the different relations they bear to each other, and to the things they represent.

CASE, among printers, denotes a sloping frame, divided into several compartments, each containing a number of types or letters of the same kind. From these compartments the compositor takes out each letter as he wants it, to compose a page or form.

CASE *of crown glass* contains 12, 15, or 18 tables, according to the quality of the glass: in cases of the best glass there are the smallest number of tables, as the price is the same for each case.

CASE *of Newcastle green glass* contains 35 tables.

CASE HARDENING, a method of preparing iron, so as to render its outer surface hard, and capable of resisting any edged tool.

CASE SHOT, in the military art, musket ball, stones, old iron, &c. put into cases, and shot out of great guns.

CASEMENT, or CASEMATE, in architecture, a hollow moulding, which some architects make one sixth of a circle, and others one fourth.

CASERN, in fortification, lodgings built in garrison towns, generally near the rampart, or in the waste places of the town, for lodging the soldiers of the garrison. There are usually two beds in each casern for six soldiers to lie, who mount the guard alternately, the third part being always on duty.

CASES, *reserved*, in the polity of the Romish church, atrocious crimes, the absolution of which is reserved by the superiors to themselves or their vicars. There are cases reserved by the pope, who formerly gave the absolution in person, but now delegates that power to certain bishops and priests: cases reserved by the bishops in convents, some by the chapters; but at the point of death all reserved cases are absolvable by the ordinary. The cases reserved by the pope, according to the ritual of Paris, are: 1. The wilful burning of churches, and also of other places, if the incendiary is publickly proclaimed. 2. Actual simony. 3. The murder or mutilation of a person in holy orders. 4. The striking a bishop or other prelate. 5. Furnishing arms to the infidels. 6. Falsifying the bulls or letters of the pope. 7. Invading or pillaging the lands of the church. 8. Violating an interdiction of the pope.

CASHEW NUT. See ANACARDIUM.

CASING *of timber work*, among builders, is the plastering a house all over on the outside with mortar, and then striking it while wet by a ruler with the corner of a trowel, to make it resemble the joints of freestone. Some direct it to be done upon heart laths, because the mortar would in a little time decay the sap laths, and to lay on the mortar in two thicknesses, *viz.* a second before the first is dry.

CASKETS, on board a ship, small ropes made of sinnet, and fastened to grommets or little rings upon the yards. Their use is to make fast the sail to the yard when it is to be furled.

CASSATION, among civilians, the act of annulling any act or procedure. The reasons of cassation are; 1. When a decree is directly contrary to another decree, and both against the same party. 2. When the decrees are contrary to the express decision of statutes and customs. 3. When the formalities prescribed by the laws have not been observed.

Cassation is properly a term in the courts of France, the laws of which country require the party that sues for a cassation, to deposite 450 livres, which sum is forfeited if he fails in his suit.

CASSIA, a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 33d order, lomentaceæ. The calyx is pentaphyllous; petals five; antheræ, upper, three barren; lower, three beaked: a leguminous plant. There are 51 species, all natives of warm climates. The most remarkable are:

1. Cassia fistula, the purging cassia of Alexandria, is a native of Egypt and both Indies: it rises to the height of 40 or 50 feet, with a large trunk, dividing into many branches with winged leaves. The flowers are produced in long spikes at the end of the branches, each standing upon a long footstalk: these are composed of fine yellow concave petals, which are succeeded by cylindrical pods from one to two feet long, with a dark brown woody shell, having a longitudinal seam on one side, divided into many cells by transverse partitions, each containing one or two oval, smooth, compressed seeds, lodged in a blackish pulp, which is the cassia used in medicine. There are two sorts of this drug in the shops, one brought from the East Indies, the other from the West. The canes or pods of the latter are generally large, rough, thick rinded, and the pulp nauseous; those of the former are less, smoother, the pulp blacker, and of a sweeter taste; this sort is preferred to the other. The pods should be chosen weighty, new, and not rattling, from the seeds being loose within them, when shaken. The pulp should be of a bright shining black colour, and a sweet taste; not harsh, which happens from the fruit being gathered before it has grown fully ripe, or sourish, which it is apt to turn upon keeping: it should neither be very dry nor very moist, nor at all mouldy; which, from its being kept in damp cellars or moistened, in order to increase its weight, it is very subject to be. The greatest part of the pulp dissolves both in water and rectified spirit; and may be extracted from the pod by either. This pulp is a gentle laxative medicine; and frequently given, in a dose of some drams, in costive habits. See Plate XXVII. Nat. Hist. fig. 93.

2. Cassia senna, is a shrubby plant cultivated in Persia, Syria, and Arabia, for the leaves, which form a considerable article of commerce. They are of an oblong figure, sharp pointed at the ends, about a quarter of an inch broad, and not a full inch in length; of a lively yellowish green colour, a faint, not very agreeable smell, and a subacrid, bitterish, nauseous taste. They are brought from the above places, dried and picked from the stalks, to Alexandria in Egypt, and thence imported into Europe. Some inferior sorts are brought from Tripoli and other places: these may easily be distinguished by their being either narrower, longer, and sharper pointed; or larger, broader, and round pointed, with small prominent veins; or large and obtuse, of a fresh green colour, without any yellow cast. Senna is a very useful cathartic, operating mildly, and yet effectually; and if judiciously dosed and managed, rarely occasioning the ill consequences which too frequently follow the exhibition of the stronger purges.

CASSIDA, in zoology, a genus of insects, of the order of the coleoptera, with filiform or threadlike antennæ; thickest toward the extremities. Add to this, that the thorax is plain and marginated. Of this genus there are many species, some green, as the viridis, some gray, but most black; but all have been confounded by authors with the beetles, and called in English tortoise beetles. Foreign countries afford many beautiful species. Even in this climate there is something singular in them. Their larva, by the help of two prongs which are found at its hinder extremity, makes itself, with its own excrements, a kind of umbrella, that shelters it from the sun and rain. When this umbrella becomes too dry, it parts with it for a new one. This larva casts its slough several times. Thistles and verticillated plants are inhabited by these insects. There is one species, of which the chrysalis resembles an armorial escutcheon. It is this which produces our variegated cassida. Numbers are found on the sides of ponds, upon the wild elecampane. See Plate XXVII. Nat. Hist. fig. 94.

CASSINE, a genus of the trigynia order, in the pentandria class of plants, and in the natural method ranking under the 23d order, dumosæ. The calyx is quinquepartite; the petals are five; and the fruit is a trispermous berry. There are four species, all of them natives of warm climates.

CASSIOPEIA, in astronomy, a constellation in the northern hemisphere, situated opposite to the Great Bear, on the other side of the pole. The stars of this constellation in Ptolemy's catalogue, are thirteen; in Tycho's twenty-eight; and in Mr. Flamsteed's fifty-six. In the year 1572 a remarkable new star appeared in this constellation, surpassing Sirius or Lyra in brightness and magnitude. It appeared even bigger than Jupiter, which, at that time, was near his perigee, and by some was thought equal to Venus when she is in her greatest lustre; but in a month it began to diminish in lustre, and in about eighteen months entirely disappeared.

CASSITERIA, in the history of fossils, a genus of crystals, the figures of which are influenced by an admixture of some particles of tin. The cassiteria are of two kinds; the whitish pellucid cassiterion, and the brown cassiterion: the first is a tolerably bright and pellucid crystal, and seldom subject to the common blemishes of crystal: it is of a perfect and regular form, in the figure of a quadrilateral pyramid, and is found in Devonshire and Cornwall principally. The brown cassiterion is like the former in figure: it is of a very smooth and glossy surface, and is also found in great plenty in Devonshire and Cornwall.

CASSOWARY. See Struthio.

CAST, or *caste*, in the East, denotes a tribe or number of families of the same rank and profession. The division of a nation into casts obtains in the dominions of the great mogul, kingdom of Bengal, and the island of Ceylon. There are four principal casts, *viz.* that of the bramins, which is the most noble; that of the rajahs, or princes, who claim to be descended from the royal families; that of the choutres, which includes artificers; and that of the parias, the lowest of all. Every art and trade is confined to its proper cast, nor can it be exercised by any but those whose fathers have professed the same. The cast of parias is held infamous; and there are trades in the cast of choutres which debase the professors of them almost to the same rank; some of which are fishermen, shoemakers, and even shepherds.

CASTANIA, chesnut, in botany, a genus of the class monoecia, order pentandria. The essential characters are; cal. five and six leaved; cor. five petaled; seed two and three, enclosed in a convex hull or bur; flowers in June. There are three species. 1. C. vesca americana, common chesnut, native of Pennsylvania and Carolina. 2. C. nana, dwarf chesnut, native of Georgia, and 3. C. pumila, chinquapin, native of Pennsylvania and Georgia. (*b*)

CASSYTA, a genus of the monogynia order, in the enneandria class of plants. The corolla is in the form of a calyx, divided into six segments; the nectarium is composed of three truncated glands encompassing the germen; the interior filaments are glandular; and the drupe contains a single seed. There are two species.

CASTILLAN, or *Castillane*, a gold coin, current in Spain, and worth fourteen rials and sixteen deniers. Castillan is also a weight used in Spain for weighing gold. It is the hundredth part of a pound Spanish weight. What they commonly call a weight of gold in Spain, is always understood of the castillan.

CASTILLEIA, a genus of the didynamia angiospermia class and order. The essential character is, calyx tubular, compressed; upper lip bifid, lower none; corolla, lower lip trifid; capsule two celled. There are two species, natives of South America.

CASTING, among sculptors, implies the taking of casts and impressions of figures, busts, medals, &c.

The art of taking casts or impressions from pieces of sculpture, medals, &c. is of very great importance in the fine arts. In order to procure a copy or cast from any figure, bust, medal, &c. it is necessary to obtain a mould, by pressing upon the thing to be moulded or copied some substance which, when soft, is capable of being forced into all the cavities or hollows of the sculpture. When this mould is dry and hard, some substance is poured into it, which will fill all the cavities of the mould, and represent the form of the original from which the mould was taken.

The particular manner of moulding depends upon the form of the subject to be worked upon. When there are no projecting parts, but such as form a right or a greater angle with the principal surface of the body, nothing more is required than to cover it over with the substance of which the mould is to be formed, taking care to press it well into all the cavities of the original, and to take it off clean, and without bending. The substances used for moulding are various, according to the nature and situation of the sculpture. If it may be laid horizontally, and will bear to be oiled without injury, plaster of Paris may be advantageously employed, which may be poured over it to a convenient thickness, after oiling it to prevent the plaster from sticking. A composition of beeswax, resin, and pitch, may also be used, which will be a very desirable mould, if many casts are to be taken from it. But if the situation of the sculpture is perpendicular, so that nothing can be poured upon it, then clay, or some similar substance, must be used. The best kind of clay for this purpose is that used by the sculptors for making their models; it must be worked to a due consistence, and having spread it out to a size sufficient to cover all the surface, it must be sprinkled over with whiting, to prevent it

from adhering to the original. Beeswax and dough, or the crumb of new bread, may also be used for moulding some small subjects. When there are undercuttings in the bas relief, they must be first filled up before it can be moulded, otherwise the mould could not be got off. When the casts are taken afterward, these places must be worked out with a proper tool.

When the model, or original subject, is of a round form, or projects so much that it cannot be moulded in this manner, the mould must be divided into several parts; and it is frequently necessary to cast several parts separately, and afterward to join them together. In this case, the plaster must be tempered with water to such a consistence, that it may be worked like soft paste, and must be laid on with some convenient instrument, compressing it so as to make it adapt itself to all parts of the surface. When the model is covered to a convenient thickness, the whole must be left at rest till the plaster is set and firm, so as to bear dividing without falling to pieces, or being liable to be put out of its form by any slight violence; and it must then be divided into pieces, in order to its being taken off from the model, by cutting it with a knife with a very thin blade; and being divided, must be cautiously taken off, and kept till dry: but it must be observed, before the separation of the parts is made, to notch them across the joints, or lines of division, at proper distances, that they may with ease and certainty be properly put together again. The art of properly dividing the moulds, in order to make them separate from the model, requires more dexterity and skill than any other thing in the art of casting, and does not admit of rules for the most advantageous conduct of it in every case. Where the subject is of a round or spheroidal form, it is best to divide the mould into three parts, which will then easily come off from the model; and the same will hold good of a cylinder, or any regular curve figure. The mould being thus formed, and dry, and the parts put together, it must be first oiled, and placed in such a position that the hollow may lie upward, and then filled with plaster mixed with water; and when the cast is perfectly set and dry, it must be taken out of the mould and repaired when necessary, which finishes the operation.

In larger masses, where there would otherwise be a great thickness of the plaster, a core may be put within the mould, in order to produce a hollow in the cast, which both saves the expense of the plaster, and renders the cast lighter.

In the same manner, figures, busts, &c. may be cast of lead, or any other metal in the moulds of plaster or clay; taking care, however, that the moulds be perfectly dry; for should there be the least moisture in them, the sudden heat of the metal would convert it into vapour, which would produce an explosion, and blow the melted metal about.

To take a cast in metal from any small animal, insect, or vegetable. Prepare a box, sufficiently large to hold the animal, which must be dead, in which it must be suspended by a string, and the legs, wings, &c. of the animal, or the tendrils, leaves, &c. of the vegetable, must be separated, and adjusted in their right position by a pair of small pincers. A due quantity of plaster of Paris mixed with talc, must be tempered to the proper consistence with water, and the sides of the box oiled. Also a straight piece of stick must be put to the principal part of the body, and pieces of wire to the extremities of the other parts, in order that they may form, when drawn out after the matter of the mould is set and firm, proper channels for pouring in the metal, and vents for the air, which otherwise, by the rarefaction it would undergo from the heat of the metals, would blow it out, or burst the mould. In a short time the plaster will set, and become hard; when the stick and wires may be drawn out, and the frame or coffin in which the mould was cast taken away; and the mould must then be put, first, into a moderate heat, and afterward when it is as dry as it can be rendered by that degree, removed into a greater, which may be gradually increased till the whole is red hot. The animal or vegetable enclosed in the mould, will then be burnt to a coal: and may be totally calcined to ashes, by blowing for some time into the charcoal and passages made for pouring in the metal, and giving vent to the air; which will, at the same time that it destroys the remainder of the animal or vegetable matter, blow out the ashes. The mould must then be suffered to cool gently, and will be perfect; the destruction of the substance included in it, having produced a corresponding hollow; but it may nevertheless be proper to shake the mould, and turn it upside down, as also to blow with the bellows into each of the air vents, in order to free it wholly from any remainder of the ashes; or where there may be an opportunity of filling the hollow with quicksilver, it will be found a very effectual method of clearing the cavity; as all dust, ashes, or small detached bodies, will necessarily rise to the surface of the quicksilver, and be poured out with it. The mould being thus prepared, it must be heated very hot, when used, if the cast is to be made with copper or brass, but a less degree will serve for lead or tin. The metal being poured into the mould, must be gently struck, and then suffered to rest till it is cold; at which time it must be carefully taken from the cast, but without force; for such parts of the matter as appear to adhere more strongly, must be softened, by soaking in water till they are entirely loosened, that none of the more delicate parts of the cast may be broken off or bent.

When talc cannot be obtained, plaster alone may be used; but it is apt to be calcined, by the heat used in burning the animal or vegetable whence the cast is taken, and to become of too incoherent and friable a texture. Stourbridge, or any other good clay, washed perfectly fine, and mixed with an equal part of fine sand, may be employed. Pounded pumice stone, and plaster of Paris, in equal quantities, mixed with washed clay in the same proportion, is said to make excellent moulds.

Method of taking a cast in plaster from a person's face. The person whose likeness is required in plaster, must lie on his back, and the hair must be tied back, so that none of it covers the face. Into each nostril convey a conical piece of stiff paper, open at both ends to allow of breathing. The face is then lightly oiled over in every part with salad oil, to prevent the plaster from sticking to the skin. Procure some fresh burnt plaster, and mix it with water to a proper consistence for pouring. Then pour it by spoonfuls quickly all over the face, taking care the eyes are shut, till it is entirely covered to the thickness of a quarter of an inch. This substance will grow sensibly hot, and in a few minutes it will be hard, and form a mould, in which a head of clay may be moulded; and therein the

eyes may be opened, and such other additions and corrections may be made as are necessary. Then, this second face being anointed with oil, another mould of plaster must be made upon it, consisting of two parts joined lengthwise along the ridge of the nose; and in this a cast in plaster may be taken, which will be exactly like the original.

To take casts from medals. In order to take copies of medals, a mould must first be made; this is generally either of plaster of Paris, or of melted sulphur.

After having oiled the surface of the medal with a little cotton, or a camel's hair pencil dipped in oil of olives, put a hoop of paper round it, standing up above the surface of the thickness you wish the mould to be. Then take some plaster of Paris, mix it with water to the consistence of cream, and with a brush rub it over the surface of the medal, to prevent air holes from appearing: then immediately afterward make it to a sufficient thickness, by pouring on more plaster. Let it stand about half an hour, and it will in that time grow so hard, that you may safely take it off; then pare it smooth on the back and round the edges neatly. It should be dried, if in cold or damp weather, before a brisk fire. If you cover the face of the mould with fine plaster, a coarser sort will do for the back: but no more plaster should be mixed up at one time than can be used, as it will soon get hard, and cannot be softened without burning over again. Sulphur must not be poured upon silver medals, as this will tarnish them.

To prepare this mould for casting sulphur or plaster of Paris in, take half a pint of boiled linseed oil, and oil of turpentine one ounce, and mix them together in a bottle; when wanted, pour the mixture into a plate or saucer, and dip the surface of the mould into it; take the mould out again; and when it has sucked in the oil, dip it again. Repeat this, till the oil begins to stagnate upon it; then take a little cotton wool, hard rolled up, to prevent the oil from sticking to it, and wipe it carefully off. Lay it in a dry place for a day or two, if longer the better, and the mould will acquire a very hard surface from the effect of the oil.

To cast plaster of Paris in this mould proceed with it in the same manner as above directed for obtaining the mould itself, first oiling the mould with olive oil. If sulphur casts are required, it must be melted in an iron ladle.

Another method with isinglass. Dissolve isinglass in water over the fire; then, with a hair pencil, lay the melted isinglass over the medal; and when you have covered it properly, let it dry. When it is hard, raise the isinglass up with the point of a penknife, and it will fly off like horn, having a sharp impression of the medal.

The isinglass may be made of any colour, by mixing the colour with it; or you may breathe on the concave side, and lay gold leaf on it, which, by shining through, will make it appear like a gold medal. But if you wish to imitate a copper medal, mix a little carmine with the isinglass, and lay gold leaf on as before.

CASTLE, in the sea language, is a part of the ship, of which there are two; the forecastle, being the elevation at the prow, or the uppermost deck, toward the mizen, the place where the kitchens are; and the hindcastle, where the officers' cabins are.

CASTOR, the *beaver*, in zoology, a genus of the order of glires. The generic character is, front teeth in the upper jaw truncated and excavated with a transverse angle; in the lower jaw transverse at the tips; grinders on each side four; tail long, depressed and scaly; collar bones in the skeleton.

1. Castor fiber, or common beaver, is a native of the most northern parts of Europe and Asia, but is found most plentifully in North America. It is readily distinguished from every other quadruped; see Plate XXVII. Nat. Hist. fig. 95; by the remarkable structure of its tail, which is of an oval form, nearly flat, but rising into a slight convexity on its upper surface, perfectly void of hair, except at the base, and marked out into scaly divisions like the skin of a fish. The general length of the beaver is about three feet, and of the tail nearly one foot. The colour of the animal is a deep chesnut, and the hair is very fine, smooth, and glossy. The beaver, like other quadrupeds, sometimes varies in colour, and is occasionally found perfectly black.

Of all quadrupeds the beaver is considered as possessing the greatest degree of natural or instinctive sagacity in constructing its habitation; preparing, in concert with others of its own species, a kind of arched caverns or domes, supported by a foundation of strong pillars, and lined or plastered internally with a degree of neatness and accuracy unequalled by the art of any other quadruped.

The favourite resorts of the beaver are retired watery, and woody, situations. In such places the animals assemble, to the number of some hundreds; living in a kind of families, and building their arched mansions or receptacles.

They begin to assemble in the month of June or July, for the purpose of uniting into society. They arrive in numbers from all parts, and soon form a troop of two or three hundred. The place of rendezvous is generally the situation fixed for their establishment, and always on the banks of some water. If the waters are flat, and never rise above their ordinary level, as in lakes, the beavers make no bank or dam; but in rivers or brooks, where the waters are subject to risings and fallings, they construct a bank, and by this artifice form a pond or piece of water, which remains always at the same height. The bank traverses the river, from one side to the other, like a sluice, and is often from eighty to a hundred feet long, by ten or twelve broad at the base. This pile, for animals of so small a size, appears to be enormous, and supposes an incredible labour; but the solidity with which the work is constructed is still more astonishing than its magnitude. The part of the river where they erect this bank is generally shallow. If they find on the margin a large tree, which can be made to fall into the water, they begin with cutting it down, to form the principal part of their work. This tree is often thicker than the body of a man. By gnawing the foot of a tree with their four cutting teeth they accomplish their purpose in a very short time, and always make the tree fall across the river. They next cut the branches from the trunk, to make it lie level. These operations are performed by the whole community. Several beavers are employed in gnawing the foot of the tree, and others in lopping off the branches after it has fallen. Others, at the same time, traverse the banks of the river, and cut down smaller trees from the size of a man's leg to that of his thigh. These they dress and cut to a certain length, to make stakes of them, and first drag

them by land to the margin of the river, and then by water to the place where the building is carrying on. These piles they sink down, and interweave the branches with the larger stakes. Whilst some are labouring in this manner, others bring earth, which they plash with their fore feet, and transport in such quantities, that they fill with it all the intervals between the piles. These piles consist of several rows of stakes, of equal height, all placed opposite to each other, and extend from one bank of the river to the other. The stakes facing the under part of the river are placed perpendicularly; but the rest of the work slopes upward to sustain the pressure of the fluid, so that the bank, which is ten or twelve feet wide at the base, is reduced to two or three at the top.

The first great structure is made with a view to render their smaller habitations more commodious. These cabins or houses are built upon piles near the margin of the pond, and have two openings, the one for going on the land, and the other for throwing themselves into the water. The form of the edifices is either oval or round, some of them larger, and some less, varying from four to five, to eight or ten feet diameter. Some of them consist of three or four stories, and their walls are about two feet thick, raised perpendicularly upon planks, or plain stakes, which serve both for foundations and floors to their houses. They are built with amazing solidity, and neatly plastered both without and within. They are impenetrable to rain, and resist the most impetuous winds. The partitions are covered with a kind of stucco, as nicely plastered as if it had been executed by the hand of man. In the application of this mortar their tails serve for trowels, and their feet for plastering. They employ different materials, as wood, stone, and a kind of sandy earth, which is not subject to dissolution in water. They labour in a sitting posture; and besides the convenience of this situation, they enjoy the pleasure of gnawing perpetually the bark and wood, which are most agreeable to their taste; for they prefer fresh bark and tender wood to most of their ordinary aliment. Of these provisions they lay up ample stores to support them during the winter; but they are not fond of dry wood, and make occasional excursions during the winter season for fresh provisions in the forests. It is in the water, or near their habitations, that they establish their magazines. Each cabin has its own magazine, proportioned to the number of its inhabitants, who have all a common right to the store, and never pillage their neighbours. Some villages are composed of twenty or twenty-five cabins, but such establishments are rare; and the common republic seldom exceeds ten or twelve families, each of which has its own quarter of the village, its own magazine, and its separate habitation. The smallest cabins contain two, four, or six; and the largest eighteen, twenty, and, it is alleged, sometimes thirty, beavers. They are almost always equally paired, there being the same number of females as of males. When danger aproaches, they warn one another by striking their tail on the surface of the water, the noise of which is heard at a great distance, and resounds through all the vaults of their habitations. Each takes his part; some plunge into the lake; others conceal themselves within their walls, which can only be penetrated by the fire of heaven or the steel of man, and which no animal will attempt either to open or overturn. They often swim a long way under the ice; and it is then that they are most easily taken, by attacking the cabin on one hand, and at the same time watching at a hole made at some distance, whither they are obliged to repair for the purpose of respiration. The continual habit of keeping their tail and posterior part in the water, appears to have changed the nature of their flesh. That of their anterior parts, as far as the reins, has the taste and consistence of the flesh of land animals; but that of the tail and hinder parts has the odour and all other qualities of fish.

Besides the associated beavers there are others that live solitary, and instead of constructing caverns, or vaulted and plastered receptacles, content themselves with forming holes in the banks of rivers. The fur of these, which are commonly termed terrier beavers, is considered as far less valuable than that of the associated animals.

The beaver when taken young may readily be tamed; and in that state appears to be an animal of a gentle disposition, but does not exhibit any symptoms of superior sagacity.

2. Castor huidobrius, or Chili beaver. This is a species peculiar to South America, and is found in the very deep lakes and rivers of that country, and feeds principally on fish and crabs. Its length from nose to tail is about three feet: the head is of a squarish form, the eyes small, the ears rounded and short, and the snout obtuse; in each jaw are two sharp and strong cutting teeth, and the grinders are like those of the common beaver. The body is very broad, and covered, like the common beaver, with two sorts of hair; the shortest or softest of which is superior to that of most other quadrupeds, and is in high esteem with manufacturers, being wrought into a kind of cloth which has the softness of velvet, and is also used in the manufacture of hats. It is a bold and even fierce animal, and has the power of continuing a great while under water. It does not construct any regular habitation like the common beaver, nor does it afford any castor. The female is said to produce from two to three young at a birth. It is called in Chili by the name of guillino.

Castor, in astronomy. See Gemini.

CASTOREUM, *castor*, in the materia medica, is by many mistaken for the spermatic matter of the animal, though, in fact, it is a peculiar secreted matter, contained in bags destined to receive it, in the manner of the musk and civet, yet situated differently in the animal.

CASUARINA, a genus of monandria order, in the monoecia class of plants. The male has the calyx of the amentum; the corolla a bipartite small scale. The female has a calyx of the amentum, no corolla; the style is bipartite. There are five species, natives of New South Wales.

CAT. See Felis.

Cat harpings, in a ship, small ropes running in little blocks from one side of the shrouds to the other, near the deck. Their use is to force the shrouds, and make them tawt, for the more security and safety of the masts.

Cat, or *cat head*, on shipboard, a short piece of timber in a ship, lying aloft right over the hawse, having at one end two shivers, wherein is reeved a rope, with a great iron hook fastened to it, called

Cat hook. Its use is to trice up the anchor, from the hawse to the top of the forecastle.

CAT HOLES, in a ship, are over the parts as right with the capstan as they can be: their use is to heave the ship astern, upon occasion, by a cable, or a hawse, called stern fast.

CATGUT, a small string for fiddles and other musical instruments, made from the intestines of sheep and lambs, dried and twisted either singly or several together. They are sometimes coloured, and are used by watchmakers, cutlers, turners, and other artificers. Great quantities are imported into England and other northern countries, from France and Italy.

CAT SALT, a name given by our salt workers to a very beautifully granulated kind of common salt. It is formed out of the bittern, or leach brine, which runs from the salt when taken out of the pans. When the common salt is taken from the boiling pans, it is put into long wooden troughs, with holes bored at the bottom for the brine to drain out: under these troughs vessels are placed to receive this brine, and across them small sticks, to which the cat salt fixes itself in large and beautiful crystals. It contains some portion of the bitter purging salt, is sharp and pungent, and is white when powdered, though pellucid in the mass. Large quantities of this salt are used in the manufacture of hard soap.

CATACAUSTIC *curves*, in the higher geometry, that species of caustic curves which are formed by reflection.

These curves are generated after the following manner. If there be an infinite number of rays, as AB, AC, AD, &c. see Plate XIV. Miscel. fig. 12. proceeding from the radiating point A, and reflected at any given curve BDH, so that the angles of incidence be still equal to those of reflection; then the curve BEG, to which the reflected rays BI, CE, DF, &c. are tangents continually, as in the points I, E, F, is the catacaustic curve.

If the reflected IB be produced to K, so that AB = BK, and the curve KL be the evolute of the catacaustic BEG, beginning at the point K; then the portion of the catacaustic BE = AC — AB + CE — BI continually. Or if any two incident rays, as AB, AC be taken, that portion of the caustic that is evolved while the ray AB approaches to a coincidence with AC, is equal to the difference of those incident rays + the difference of the reflected rays. When the given curve is a geometrical one, the catacaustic will be so too, and always rectifiable.

The catacaustic of a circle is a cycloid formed by the revolution of a circle along a circle. The caustic of the vulgar semi-cycloid, when the rays are parellel to the axis, is also a vulgar cycloid, described by the revolution of a circle upon the same base. The caustic of the logarithmic spiral is the same curve, only set in a different position.

CATACHRESIS, in rhetoric, a trope which borrows the name of one thing to express another.

CATACOMB, a grotto or subterraneous place for the burial of the dead. The term is particularly used in Italy for a vast assemblage of subterraneous sepulchres, three leagues from Rome, in the *via Appia*, supposed to be the sepulchres of the ancients. Others imagine these catacombs to be the cells wherein the primitive Christians hid themselves. Each catacomb is three feet broad, and eight or ten high, running in form of an alley or gallery, and communicating with one another. Some authors suppose them to have been the *puticuli* mentioned by Festus Pompeius, into which the Romans threw the bodies of their slaves, to whom they denied the honours of burying; and Mr. Monro, in the Philosophical Transactions, gives it as his opinion, that the catacombs were the burial places of the first Romans, before the practice of burning the dead was introduced; and that they were dug in consequence of these opinions, that Shades hate the light, and love to hover about the places where their bodies were laid.

The catacombs of Egypt seem to be of a different nature, though called by the same name. The bodies found in these catacombs are mummies. In searching for these, labourers are frequently obliged to clear away the sand for weeks together, before they find the precious deposite. Upon coming to a square opening of about eighteen feet in depth, they descend into it by holes made for the feet, placed at proper distances, and there they are sure of finding a mummy. These caves, or wells, as they are usually called, are hollowed out of freestone, which is found in Egypt a few feet below the covering of sand. At the bottom of these, which are about forty feet below the surface, there are several square openings on each side of the passages, often or fifteen feet wide, and these lead to chambers of fifteen or twenty feet square, hewn out of the rock; and in each of the catacombs are to be found several apartments communicating with one another. They are said to extend so far as to undermine the city of Memphis and its environs. In some of these chambers the walls are adorned with figures and hieroglyphics; in others the mummies are found in tombs, round the apartment, hollowed out in the rock.

CATALEPSY, in medicine, a kind of apoplexy, or drowsy disease, in which the patient is taken speechless, senseless, and fixed in the same posture in which the disease first seized him. See MEDICINE.

CATALOGUE *of the stars*. See ASTRONOMY.

CATANANCHE, *Candia lion's foot*, a genus of the polygamia æqualis order, in the syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The receptacle is paleaceous; the calyx is imbricated; the pappus furnished with awns by a caliculas of five stiff hairs. There are three species, of which the most remarkable is the

Catananche cerulea, which is a hardy, herbaceous, and very ornamental plant for the flower garden. There is a variety with double flowers.

CATAPHONICS, the science which considers the properties of reflected sounds. See PNEUMATICS.

CATAPHRACTA, in antiquity, a kind of coat of mail, which covered the soldier from head to foot. Hence cataphractati were horsemen armed with the cataphracta, whose horses, as Sallust says, were covered with linen full of iron plates disposed like feathers.

CATAPHRYGIANS, ancient heretics, who took their name from the country of Phrygia. They supposed the Holy Spirit had abandoned the church, and therefore that Montanus, as a prophet, and Priscilla and Maximilla, as true prophetesses, were to be consulted in every thing relating to religion.

CATAPLASM, an external topical medicine, of a soft consistence, known by the common name of poultice, and prepared of ingredients of different virtues, according to the intention of the physician. See PHARMACY.

CATAPULTA, in antiquity, a military engine contrived for the throwing of arrows, darts, and stones, upon the enemy. Some of these engines were of such force, that they would throw stones of an hundred weight. Josephus takes notice of the surprising effects of these engines, and says, that the stones thrown out of them beat down the battlements, knocked off the angles of the towers, and would level a whole file of men, from one end to the other, were the phalanx ever so deep.

CATARACT, in hydrography, a precipice in the channel of a river, caused by rocks, or other obstacles, stopping the course of the stream, whence the water falls with a greater noise and impetuosity: such are the cataracts of the Nile, the Danube, the Rhine, and the famous one of Niagara in America.

CATARACT. See SURGERY.

CATARRH, in medicine, a defluxion from the head upon the mouth and aspera arteria, and through them upon the lungs. See MEDICINE.

CATECHU, in the materia medica, improperly called terra japonica in the shops, is a concreted vegetable juice, partly of the gummy, partly of the resinous kind. See ARECA, and MATERIA MEDICA.

CATEGORY, in logic, a series or order of all the predicates or attributes contained under any genus.

The school philosophers distribute all the objects of our thoughts and ideas into certain genera or classes; and these classes the Greeks call categories, and the Latins predicaments. Aristotle made ten categories, *viz.* quantity, quality, relation, action, passion, time, place, situation, and habit, which are usually expressed by the following technical distich.

Arbor, sex, servos, ardore, refrigerat, ustos,
Ruri cras stabo, nec tunicatus ero.

CATENARIA, in the higher geometry, the name of a curve line formed by a rope hanging freely from two points of suspension, whether the points be horizontal or not. The nature of this curve was sought after in Galileo's time, but not discovered till the year 1690, when James Bernouilli published it as a problem. Dr. Gregory, in 1697, published a method of investigation of the properties formerly discovered by John Bernouilli and Mr. Leibnitz, together with some new properties of this curve. From him we take the following method of finding the general property of the catenaria. 1. Suppose a line heavy and flexible, the two extremes of which F and D, Plate XIV. Miscel. fig. 13. are firmly fixed in these points; by its weight it is bent into a certain curve F A D, which is called the catenaria. 2. Let B D and $b\,c$ be parallel to the horizon, A B perpendicular to B D, and D c parallel to A B, and the points B b infinitely near to each other. From the laws of mechanics, any three powers in equilibrio, are to one another as the lines parallel to the lines of their direction, or inclined in any given angle, and terminated by their mutual concourses: hence if D d express the absolute gravity of the particle D d, as it will if we allow the chain to be every way uniform, then D c will express that part of the gravity that acts perpendicularly upon D d; and by the means of which this particle endeavours to reduce itself to a vertical position; so that if this little line $d\,c$ be constant, the perpendicular action of gravity upon the parts of the chain, will be constant too, and may therefore be expressed by any given right line.

Further, the lineola D c will express the force which acts against that conatus of the particle D d, by which it endeavours to restore itself into a position perpendicular to the horizon, and hinders it from doing so. This force proceeds from the ponderous line D A drawing according to the direction D d; and is, cæteris paribus, proportional to the line D A which is the cause of it. Supposing the curve F A D, therefore, as before, whose vertex is A, axis A B, ordinate B D, fluxion of the axis D c = B b, fluxion of the ordinate $d\,c$, the relation of these two fluxions is thus, *viz.* $d\,c$: D d :: a: D A curve, which is the fundamental property of the curve, and may be thus expressed (putting A B = x and B D = y and A D = c)

$$y = \frac{ax}{c}.$$

CATERGI, the name of the public carriers in the grand seignior's dominions. In Europe, the merchant or traveller gives earnest to the carrier, but the catergi in Turkey give earnest to the merchant and others, as a security that they will certainly carry their goods, or not set out with them.

CATERPILLAR, in zoology, the name of the butterfly class of insects, in their reptile or worm state. See PAPILIO, &c.

CATESBÆA, the lily thorn, a genus of the monogynia order, in the tetrandria class of plants; and in the natural method ranking under the 28th order, luridæ. The corolla is monopetalous, funnel shaped, very long above the receptacle of the fruit; the stamina are within its throat; the fruit a polyspermous berry. There are two species, *viz.* the

1. Catesbæa spinosa, a native of the island of Providence, discovered by Mr. Catesby, who gathered the seeds, and brought them to England. It rises to the height of ten or twelve feet, and is covered with a pale russet bark, with small leaves resembling those of the box tree; the flowers hang downward, are tubulous, and of a dull yellow colour. This plant is propagated by seeds, which must be procured from the country where it grows. 2. The catesbæa parviflora.

CATHARINE, or knights of St. Catharine, a military order, instituted for the security of travellers who came to visit the tomb of this saint on mount Sinai.

CATHARISTÆ, in church history, a branch of Manichees, so called from certain purifications which they were obliged to practise; they are also said to have held it unlawful to eat flesh.

CATHARTICS. See MATERIA MEDICA.

CATHETER. See SURGERY.

CATHETUS, in geometry, a line or radius falling perpendicularly on another line or surface: thus the catheti of a right angled triangle are the two sides that include the right angle.

CATHETUS, in architecture, a perpendicular line, supposed to pass through the middle of a cylindrical body, as a baluster, column, &c.

CATOPTRICS. See OPTICS.

CATTLE. By the 3 and 4 Edward VI. c. 19. no person shall buy any ox, steer, runt, or cow, &c. and sell

the same again alive in the same market, or fair, on pain of forfeiting double the value thereof, half to the king, and half to him that shall sue. This is the only act in force against forestalling, engrossing, and regrating.

If any person shall feloniously drive away, or steal, or shall wilfully kill any ox, bull, cow, calf, steer, bullock, heifer, sheep or lamb, with a felonious intent to steal the whole carcass, or any part thereof, or shall assist in committing any such offence, he shall be guilty of felony without benefit of clergy. 14 and 15 George II. c. 6. and 34.

Any person, who shall unlawfully and maliciously kill, maim, or wound any cattle, shall be guilty of felony without benefit of clergy; and the hundred shall be answerable for the damages, not exceeding 200*l.* 9 George, c. 22. And horses, mares, and colts, are included in the word cattle. Every person who shall apprehend and prosecute to conviction any offender, shall have ten pounds reward; to be paid by the sheriff within a month, on his producing a certificate from the judge. The 26 George III. c. 71. to prevent the stealing of horses, &c. for their skin, provides that all persons keeping a slaughter house for cattle not killed for butcher's meat, shall take out licenses, be subject to an inspector, and only slaughter at certain times.

CATURUS, a genus of the dioecia triandria class and order. There are two species, natives of the East Indies.

CAVA, or vena cava. See ANATOMY.

CAVALIER, in fortification, an elevation of earth, of different shapes, situated ordinarily in the gorge of a bastion, bordered with a parapet, and cut into more or less embrasures, according to the capacity of the cavalier.

Cavaliers are a double defence for the faces of the opposite bastion: they defend the ditch, break the besiegers' galleries, command the traverses in dry moats, scour the salient angle of the counterscarp where the besiegers have their counter batteries, and enfilade the enemies' trenches, or oblige them to multiply their parallels; they are likewise very serviceable in defending the breach, and the retrenchments of the besieged, and can very much incommode the entrenchments which the enemy make by their being lodged in the bastion.

CAVAZION, or cavasion, in architecture, denotes the hollow trench made for laying the foundation of a building, which, according to Palladio, ought to be one sixth part of the height of the whole building.

CAUCALIS, in botany, a genus of the pentandria digynia class of plants, the universal flower of which is difform and radiated; the proper flower of the disk is male, small, composed of five inflexo cordated equal petals; the fruit is of an oblato oblong figure, striated longitudinally, with rigid scabrous bristles: the seeds are two, oblong, convex on one side and armed with prickles in order of the striæ, and plane on the other side. There are nine species.

CAUDA *draconis*, the dragon's tail, in astronomy, the name of the moon's descending node.

CAUDA *leonis*, in astronomy, a star of the first magnitude in the tail of the constellation Leo. See LEO.

CAVEAR, *caveer*, or *caviar*, the spawn or hard roes of sturgeon, made into small cakes, an inch thick, and of a hand's breadth, salted and dried in the sun. This sort of food is in great repute throughout Muscovy, because of their three Lents, which they keep with a superstitious exactness.

CAVEAT, is a caution, entered in the spiritual court, to stop probates, administrations, licenses, dispensations, faculties, institutions, and such like, from being granted without the knowledge of the party that enters it. A caveat stands in force for three months. 2 Rol. Rep. 6.

The entering a caveat being at the instance of the party, is only for the benefit of the ordinary, that he may do no wrong; it is a cautionary act for his better information, to which the temporal courts have no manner of regard; therefore if after a caveat entered, the ordinary should grant administration, or probate of a will, it is not void by our law; it is true it is void by the canon law, but our law takes no notice of a caveat. Rol. Rep. 191.

CAVEDO, in commerce, a Portuguese long measure, equal to $27\frac{354}{1000}$ English inches.

CAVETTO, in architecture, a hollow member, or round concave moulding, containing a quadrant of a circle, and having a quite contrary effect to that of a quarter round; it is used as an ornament in cornices.

CAVIA, a genus of the order of glires. The generic character is, front teeth two, wedge shaped; grinders eight; toes on the fore feet from four to five, on the hind feet from three to five; tail very short, or none; clavicles, or collar bones, none. The animals of the genus cavia have generally a slow, and sometimes a leaping pace: they live like the rest of the glires, on vegetable substances, and in their natural state inhabit excavations under ground, or beneath the roots of trees; or other recesses which they either find ready prepared, or form for themselves. The most familiar example of this genus is the well known little animal, called the guinea pig, or

1. Cavia cobaya, or variegated cavy. This little animal is very easily rendered tame, but is seldom observed to show any very lively attachment to its benefactors; and is not distinguished by any remarkable degree of docility: it is, however, cleanly, harmless, and of a timid disposition. In a state of confinement it breeds almost every two months; and often produces a very numerous offspring at a birth. The young very soon acquire the necessary degree of strength and perfection of their species, though they continue to grow till seven or eight months. In their habits they are extremely neat, and may be frequently observed in the act of smoothing and dressing their fur, somewhat in the manner of a cat. In their quarrels they not only bite but kick each other, like horses, with their hind feet. It is observed that the male and female seldom sleep at the same time; but seem alternately to watch each other; the one sleeping while the other is feeding, &c. Their general voice is a sort of grunting squeak, and sometimes a shriller or sharper cry.

2. Cavia paca, or spotted cavy. This is a large species, Plate XXVII. Nat. Hist. fig. 98. measuring near two feet in length. It is found in Guiana, Brazil, and other parts of South America; inhabiting holes, formed under ground, and principally near the banks of rivers. It is of a thick, clumsy form, somewhat resembling that of a pig; for which reason it has been sometimes called the hog rabbit. The spotted cavy is a nocturnal animal, residing in a solitary manner in his hole during almost the whole day. In a domestic state it readily feeds on almost any kind of vegetable diet, and is particularly fond of sugar and fruits.

It is much esteemed as an article of food by the South Americans. It is subject to some variety in point of colour, and has been sometimes seen quite white. Its general length, when full grown, is about two feet. The female is said to produce but one young at a birth.

3. Cavia capybara. The characters of this animal, Plate XXVII. Nat. Hist. fig. 97. are somewhat ambiguous, and it was formerly considered by Linnæus as a species of hog, and was accordingly placed in that genus in the 12th edition of the Systema Naturæ, under the name of sus hydrochœris. It grows to the size of a hog of two years old, and is said to have been sometimes found of the weight of 100 pounds. It inhabits various parts of South America, though said to be more common in Brazil than in other regions. It feeds not only on various vegetables, and particularly on sugar canes, but also, contrary to the nature of most of the glires, on fish; for which purpose, it frequents rivers, swimming with the same facility as the otter, and, like that animal, dragging its prey out of the water, and eating it on the bank.

4. Cavia caudata aguti. This species is peculiar to the warmer parts of South America, and is extremely common in Guiana. Its general size is that of a rabbit: the body is plump, and thicker behind than before: the head is rather small, and somewhat compressed laterally. This animal's manner of moving resembles that of a hare, and its voice is like the grunting of a young pig. It feeds on various roots, nuts, fruit, &c. and resides in woods, where it forms subterraneous burrows, and sometimes lodges in the hollows of trees. They are taken in traps, or hunted with dogs. The Indians and negroes, who know how to allure them by whistling, or imitating their cries, kill as many as they please. When pursued, they conceal themselves, like rabbits, in the holes of old trees. They hold their food in their paws like squirrels.

5. C. Aguti Leporine; Leporine cavy, is probably a variety of the aguti, from which it differs in being of a reddish colour above, with the breast and belly white. It is of the size of a hare, and is a native of Surinam, and other parts of South America. It is altogether an American animal, and, notwithstanding its common title of the Java hare, is not found either in that island or Sumatra, as erroneously supposed by some.

6. Cavia acuschy, Plate XXVII. Nat. Hist. fig. 96. is by some regarded as a variety of the aguti, but differs in being somewhat smaller, rather thinner, and entirely of an olive colour, paler or more inclining to whitish beneath: the tail is also longer than in the aguti. It is a native of the same parts of South America with the aguti, is of similar manners, and is also tamed with equal readiness.

7. Cavia aperea, or rock cavy. This animal, which is a native of Brazil, is neither a rabbit nor a rat, but seems to partake of both. Its general colour is the same with that of our hares, and its belly is white: its upper lip is divided in the same manner, and it has the same large cutting teeth, and whiskers round the mouth and on the sides of the eyes, but its ears are rounded like those of a rat, and so short that they exceed not a finger's breadth in height.

CAUKING, or caulking of a ship, is driving oakum, or the like, into all the seams of the planks of a ship, to prevent leaking, and keep out the water. After the seams are stopped with oakum, it is done over with a mixture of tallow, pitch, and tar, as low as the ship draws water.

CAULICOLES, or caulicoli, are eight lesser branches or stalks, in the Corinthian capital, springing out from four greater or principal cauls, or stalks. The eight volutes of this order are sustained by four cauls, or primary branches, of leaves, and from which these caulicoles or lesser foliages arise.

CAULIFEROUS, an appellation given to such plants as have a perfect caulis or stem. See Botany.

CAULIFLOWERS. See Brassica.

CAULINIA, in botany, a genus of the monoecia class, monandria order; cal. none; cor. none; capsule ovate, one celled. There are 2 species, 1. C. flexilis, bending caulinia. 2. C. fragilis, brittle caulinia; both natives of Pennsylvania; flowers in September. (*b*)

CAULOPHYLLUM *thalictroides*, in botany, a plant of the class hexandria, order monogynia; the cal. is 5 leaved, cor. 6 petaled, drupa globose, 1 celled, persisting; grows in Pennsylvania and Ohio. (*b*)

CAUSALTY, among the miners, denotes the lighter, sulphureous, earthy parts of ores, carried off in the operation of washing. This, in the mines, they throw in heaps upon banks, which, in six or seven years, they find it worth their while to work over again.

CAUSTICS. See Surgery.

Caustic curve, in the higher geometry, a curve formed by the concourse or coincidence of the rays of light, reflected from some other curve.

CAUTERY, a medicine for burning, eating, or corroding, any solid part of the body. See Surgery.

CAUTION, in the civil and Scotch law, denotes much the same with what, in the law of England, is called bail.

CAXA, a little coin made of lead, mixed with some scoria of copper, struck in China, but current chiefly at Bantam in the island of Java, and some of the neighbouring islands. The caxas are of two kinds, great and small. Of the small 300,000 are equal to fifty-six livres five sols French money; and of the great 6,000 are equal to four shillings and sixpence sterling.

CAZEMATE, or casemate, in fortification, a certain retired platform in the flank of a bastion, for the defence of the moat and face of the opposite bastion. Sometimes there are three such platforms, one behind another, the uppermost of which is on the terre plein of the bastion, which makes the other two to be called places basses, or low places. They are covered from the enemies' batteries by a work of earth added to the angle of the shoulder, of a circular and sometimes of a square form, called shoulder, orillon, or epaulement.

Cazemate, is also used for a well with several subterraneous branches dug in the passage of the bastion, till the miner is heard at work, and air given to the mine.

CEANOTHUS, New Jersey tea, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 43d order, dumosæ. There are five petals, pouched and arched. The fruit is a dry, trilocular, and trispermous berry. There are six species, of which the most remarkable is the

Ceanothus Americanus, a native of most parts of North America, whence the seeds have been imported into Europe. In England this plant seldom rises more than three

feet high. The stem, which is of a pale brown colour, sends out branches from the bottom. The flowers grow at the ends of the twigs in clusters: they are of a white colour, and when in flower give the shrub a most beautiful appearance.

CECROPIA, a genus of the diandria order in the dioecia class of plants; and in the natural method ranking under the 53d order, scabridæ. There is one species, a tree of South America.

CEDAR. See JUNIPERUS, PINUS, CEDRELA, &c.

CEDAR, *bastard*. See THEOBROMA.

CEDAR, *white*. See CUPRESSUS.

CEDRELA, a genus of the monogynia order, in the pentandria class of plants; and ranking, according to the natural method, under the 54th order, miscellaneæ. There is only one species, called Barbadoes bastard cedar.

CELARENT, in logic, a mode of syllogism, wherein the major and conclusion are universal negative propositions, and the minor an universal affirmative. As

CE No man that is a hypocrite can be saved:
LA Every man who with his lips only cries Lord, Lord, is a hypocrite:
RENT Therefore, no man, who with his lips only cries Lord, Lord, can be saved.

CELASTRUS, the staff tree, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 43d order, dumosæ. The corolla is pentapetalous and patent; the capsule quinquangular and trilocular; the seeds veiled. There are 22 species, two of which are inured to our climate, *viz.*

1. Celastrus bullatus, an uncertain deciduous shrub, a native of Virginia. It is about four feet high. The flowers are produced in July, at the ends of the branches, in loose spikes. They are of a white colour, and in their native countries are succeeded by beautiful scarlet fruit; but with us this seldom happens.

2. Celastrus scandens, the flowers of which are green, and appear in June. The berries are red, and make a fine appearance in autumn.

CELESTINS, in church history, a religious order of Christians, reformed from the Bernardins by pope Celestin V.

The celestins rise two hours after midnight to say matins: they eat no flesh any time, except when they are sick; they fast every Wednesday and Friday to the feast of the exaltation of the holy cross; and from that feast to Easter, every day.

CELIAC, or cœliac passion. See MEDICINE.

CELLEPORÆ, a genus of marine plants, or rather animals; a class of worms in the Linnæan system. They are of the order of the lythophyta.

CELOSIA, cock's comb, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 54th order, miscellaneæ. The calyx is triphyllous; the corolla is five petaled in appearance; the stamina are conjoined at the base to the plated nectarium; the capsule gaping horizontally. There are 14 species, of which the most worthy of notice is the

Celosia cristata, or common cock's comb. The principal colours of its flowers are red, purple, yellow, and white; but there are some whose heads are variegated with two or three colours. They are very tender exotics, and require a great deal of care to cultivate them in this country.

CELSIA, a genus of the angiospermia order, in the didynamia class of plants; and in the natural method ranking under the 28th order, luridæ. The calyx is quinquepartite; the corolla wheel shaped; the filaments bearded or woolly; the capsule bilocular. There are four species, natives of Armenia.

CELTIS, the lote, or nettle tree, a genus of the monoecia order, in the polygamia class of plants; and in the natural method ranking under the 53d order, scabridæ. It is an hermaphrodite plant: the female calyx is quinquepartite; there is no corolla; there are five stamina, and two styles. The fruit is a monospermous plum. In the male, there is no calyx: the corolla is hexapetalous; there are six stamina, and an embryo of a pistillum. There are seven species, all of them deciduous. The most remarkable are

1. Celtis australis, the southern celtis, a deciduous tree, a native of Africa and the south of Europe.

2. Celtis occidentalis, the western celtis, a native of Virginia. These two species grow with large, fair, straight stems. The leaves are late in the spring before they show themselves; but they make amends for this, by retaining their verdure till near the close of autumn: and then do not resemble most deciduous trees, whose leaves show their approaching fall by the change of their colour; but continue to exhibit themselves of a pleasant green to the last. Hanbury speaks highly of the celtis as a timber tree: he says, "the wood of the lote tree is extremely durable. In Italy they make their flutes, pipes, and other wind instruments of it. With us the coach makers use it for the frames of their vehicles."

3. Celtis orientalis, the eastern celtis, a native of Armenia: it grows to about 12 feet, and its branches are numerous, smooth, and of a greenish colour. The leaves are smaller than those of the others, though they are of a thicker texture, and a lighter green. The flowers come out from the wings of the leaves, on slender footstalks: they are yellowish, appear early in spring, and are succeeded by large yellow fruit.

CEMENT, any glutinous substance capable of uniting and keeping things together by cohesion. We shall give an account of some of the best compositions used for the purpose of cementing together various articles.

Jeweller's cement; for setting precious stones when pieces are broken off by accident. In such cases the artist can frequently join the pieces so correctly than an inexperienced eye cannot discover the stone to have been broken; for this purpose a small piece of gum mastich is applied between the fragments, which are previously heated sufficiently to melt the interposed gum. They are then pressed together, to force out the redundant quantity of gum.

Turkey cement, for joining metals, glass, &c. Dissolve five or six bits of mastich, as large as peas, in as much spirit of wine as will suffice to render it liquid; in another vessel dissolve as much isinglass, which has been previously soaked in water till it is swollen and soft, in brandy or rum, as will make two ounces by measure of strong glue, and add two small bits of gum galbanum, or ammoniacum, which must be rubbed or ground till they are dissolved; then mix the whole with a sufficient heat;

keep it in a phial stopped, and when it is to be used set it in hot water.

A cement for broken china, glass, &c. Take quicklime and white of eggs, or old thick varnish; grind and temper them well together, and it is ready for use. Drying oil and white lead are also frequently used for cementing china and earthen ware; but this cement requires a long time to dry. Where it is not necessary the vessel should endure heat or moisture, isinglass glue, with a little tripoli, or chalk, is better.

A cement useful for turners. Take resin one pound, pitch four ounces; melt these together, and, while boiling hot, add brickdust, until by dropping a little upon a stone, you perceive it hard enough; then pour it into water, and immediately make it up in rolls, and it is fit for use. Or take resin one ounce, pitch two ounces; add red ochre, finely powdered, until you perceive it strong enough. Sometimes a small quantity of tallow is used, according to the heat of the weather, more being necessary in winter than in summer. Either of these cements is of excellent use for turners. By applying it to the side of a chuck, and making it warm before the fire, you may fasten any thin piece of wood, which will hold while you turn it; when you want it off again, strike it on the top with your tool, and it will drop off immediately.

A strong cement for electrical purposes. Melt one pound of resin in a pot or pan, over a slow fire; add thereto as much plaster of Paris, in fine powder, as will make it hard enough, which you may soon know by trial; then add a spoonful of linseed oil, stirring it all the while, and try if it be hard and tough enough for your purpose; if it is not sufficiently hard, add more plaster of Paris; and if not tough enough, a little more linseed oil. This is as good a cement as possible for fixing the necks of globes or cylinders, or any thing else that requires to be strongly fixed; for it is not easily melted again when cold. Or take resin one pound, beeswax one ounce; add thereto as much red ochre as will make it of sufficient stiffness; pour it into water, and make it into rolls, and it is fit for use. This cement is useful for cementing hoops on glasses, or any other mounting of electrical apparatus.

A cement for glass grinders. Take pitch and boil it; add thereto, and keep stirring it all the while, fine sifted wood ashes, until you have it of a proper temper: a little tallow may be added, as you find necessary. For small work: to four ounces of resin add one fourth of an ounce of beeswax melted together; and four ounces of whitening, made previously red hot. The whitening should be put in while hot, that it may not have time to imbibe moisture from the atmosphere.

Shell lac is a very strong cement for holding metals, glass, or precious stones, while cutting, turning, or grinding them. The metal, &c. should be warmed, to melt it. For fastening ruby cylinders in watches, and similar delicate purposes, shell lac is excellent.

To solder or cement broken glass. Broken glass may be soldered or cemented in such a manner as to be as strong as ever, by interposing between the parts, glass ground up like a pigment, but of easier fusion than the pieces to be joined, and then exposing them to such a heat as will fuse the cementing ingredient, and make the pieces agglutinate without being themselves fused. A glass for the purpose of cementing broken pieces of flint glass, may be made by fusing some of the same kind of glass previously reduced to powder, along with a little red lead and borax, or with the borax only.

Cement for Derbyshire spar and other stones. A cement for this purpose may be made with about seven or eight parts of resin and one of beeswax, melted together with a small quantity of plaster of Paris. If it is wished to make the cement fill up the place of any small chips that may have been lost, the quantity of plaster must be increased a little. When the ingredients are well mixed, and the whole is nearly cold, the mass should be well kneaded together. The pieces of spar that are to be joined, must be heated until they will melt the cement, and then pressed together, some of the cement being previously interposed. Melted sulphur applied to fragments of stones previously heated, by placing them before a fire, to at least the melting point of sulphur, and then joined with the sulphur between, makes a pretty firm and durable joining. Little deficiencies in the stone, as chips out of corners, &c. may also be filled up with melted sulphur, in which some of the powder of the stone has been melted.

A cement that will stand against boiling water, and the pressure of steam. In joining the flanches of iron cylinders, and other parts of hydraulic and steam engines, great inconvenience is often experienced from the want of a durable cement. Boiled linseed oil, litharge, and red and white lead, mixed together to a proper consistence, and applied on each side of a piece of flannel previously shaped to fit the joint, and then interposed between the pieces before they are brought home, as the workmen term it, to their place by the screws or other fastenings employed, make a close and durable joint.

The quantities of the ingredients may be varied without inconvenience, only taking care not to make the mass too thin with oil. It is difficult in many cases instantly to make a good fitting of large pieces of iron work, which renders it necessary sometimes to join and separate the pieces repeatedly, before a proper adjustment is obtained. When this is expected, the white lead ought to predominate in the mixture, as it dries much slower than the red. A workman, knowing this fact, can be at little loss in exercising his own discretion in regulating the quantities. It is safest to err on the side of the white lead, as the durability of the cement is no way injured by it, only a longer time is required for it to dry and harden. When the fittings will not admit easily of so thick a substance as flannel being interposed, linen may be substituted, or even paper or thin pasteboard.

This cement answers well also for joining broken stones, however large. Cisterns built of square stones put together with this cement, will never leak, or want any repairs. In this case the stones need not be entirely bedded in it: an inch, or even less, of the edges that are to lie next the water, need only be so treated; the rest of the joint may be filled with good lime.

Another cement that will stand the action of boiling water and steam. This cement, which is preferable even to the former for steam engines, is prepared as follows: Take two ounces of sal ammoniac, one ounce of flowers of

sulphur, and 16 ounces of cast iron filings or borings. Mix all well together by rubbing them in a mortar, and keep the powder dry.

When the cement is wanted for use, take one part of the above powder, and twenty parts of clean iron borings or filings, and blend them intimately by grinding them in a mortar. Wet the compound with water, and when brought to a convenient consistence, apply it to the joints with a wooden or blunt spatula. By a play of affinities, which those who are at all acquainted with chymistry will be at no loss to comprehend, a degree of action and re-action takes place among the ingredients, and between them and the iron surfaces, which at last causes the whole to unite as one mass. In fact, after a time, the mixture and the surfaces of the flanches become a species of pyrites, holding a very large proportion of iron, all the parts of which cohere strongly together.

Blood cement. A cement often used by coppersmiths to lay over the rivets and edges of the sheets of copper in large boilers, to serve as an additional security to the joinings, and to secure cocks, &c. from leaking, is made by mixing pounded quicklime with ox's blood. It must be applied fresh made, as it soon gets hard. If the properties of this cement were duly investigated, it would probably be found useful for many purposes to which it has never yet been applied. It is extremely cheap, and very durable.

Flour paste. Flour paste for cementing, is formed principally of wheaten flour, boiled in water till it is of a glutinous or viscid consistence. It may be prepared of these ingredients, simply for common purposes; but when it is used by bookbinders, or for paper hangings, it is usual to mix with the flour a fifth or sixth of its weight of powdered resin or alum; and where it is wanted still more tenacious, gum arabic, or any kind of size, may be added.

Japanese cement, or *rice glue.* This elegant cement is made by mixing rice flour intimately with cold water, and then gently boiling it. It is beautifully white, and dries almost transparent. Papers pasted together by means of this cement will sooner separate in their own substance than at the joining, which makes it useful in the preparation of curious paper articles, as tea trays, ladies' dressing boxes, and other articles that require layers of paper to be cemented together.

CENCHRUS, in botany, a genus of the polygamia monoecia class of plants. There are two flowers, the one male, the other hermaphrodite; the proper flower is single with two lanceolated, acuminated, concave valves: there is no pericarpium, and but one roundish seed. There are eleven species.

CENSOR, in Roman antiquity, a magistrate whose business it was to reform the manners and to value the estates of the people.

CENSUS, in Roman antiquity, an authentic declaration made before the censors, by the several subjects of the empire, of their respective names and places of abode. This declaration was registered by the censors, and contained an enumeration in writing of all the estates, lands, and inheritances, they possessed; their quantity, quality, place, wives, children, domestics, tenants, slaves.

CENT, in commerce, an abridgment of centum, is used to express the profit or loss arising from the sale of any commodity: thus we say, there is 10 *per cent.* profit, or 10 *per cent.* loss; which is $\frac{1}{10}$ profit, or $\frac{1}{10}$ loss, upon the sale of the whole. In the trade of money, it signifies the benefit or interest of any sum of money. Thus money is worth 4 or 5 *per cent.* upon exchange. But in brokerage, it must be observed, that cent. is applied in a different manner. For example, if a broker or exchange agent takes $\frac{1}{8}$ *per cent.* for the contracts made by his interposition, it is to be understood that there is paid to him $\frac{1}{8}$ of a pound, *viz.* 2*s.* 6*d.* for every 100*l.* he negotiated.

CENTAUR, *centaurus*, in astronomy, a constellation of the southern hemisphere commonly joined with the wolf, and called *centaurus cum lupo.* In Ptolemy's catalogue, it consists of 37 stars; in Tycho's of 4; and of 35 in the Britannic catalogue, with Sharp's appendix.

CENTAUREA, a genus of the polygamia frustranea order, in the syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The receptacle is bristly, the pappus simple, the corollulæ of the radius funnel shaped, longer than those of the disk, and irregular. There are 77 species, of which we shall only mention two, *viz.*

1. Centaurea cyanus, the blue bottle, grows commonly among corn. The expressed juice of this flower stains linen of a beautiful blue colour, but is not permanent. Mr. Boyle says, that the juice of the inner petals, with a little alum, makes a beautiful permanent colour, equal to ultramarine.

2. Centaurea glastifolia. The root of this species is an article in the materia medica. It has a rough, somewhat acrid taste, and abounds with a red viscid juice. Its rough taste had gained it some esteem as an astringent; its acrimony as an aperient; and its glutinous quality as a vulnerary: but the present practice takes very little notice of it.

CENTIPES, in zoology. See SCOLOPENDRA.

CENTNER, among metallurgists and assayers, denotes a weight divisible first into a hundred, and afterward into other lesser parts. It is, however, to be observed, that the centner of metallurgists is the same with the common hundred weight; whereas that of assayers is no more than one dram, to which the other parts are proportional, and nevertheless pass by the names 100lb. 64lb. 32lb. &c.

CENTRAL *forces*, the powers which cause a moving body to tend toward, or recede from, the centre of motion. See MECHANICS.

CENTRE *of a bastion*, a point in the middle of the gorge of a bastion, whence the capital line commences, and is generally at the angle of the inner polygon.

CENTRE *of a conic section*, a point in which the diameters intersect each other. In the ellipsis, this point is within the figure, and in the hyperbola, without.

CENTRE *of a curve of the higher kind*, the point where two diameters concur. When all the diameters concur in the same point, sir Isaac Newton calls it the general centre.

CENTRE *of a dial*, that point where the axis of the world intersects the plane of the dial; and therefore in dials that have centres, it is that point wherein all the hour lines meet. All dials have centres, except such as have their planes parallel to the axis of the world.

CENTRE *of gravity*, in mechanics, that point about which all the parts of a body, in any situation, balance

each other. Hence, 1. If a body is suspended by this point as the centre of motion, it will remain at rest in any position indifferently. 2. If a body is suspended in any other point, it can rest only in two positions, *viz.* when the centre of gravity is exactly above or below the point of suspension. 3. When the centre of gravity is supported, the whole body is kept from falling. 4. Because this point has a constant endeavour to descend to the centre of the earth, therefore, 5. When the point is at liberty to descend, the whole body must also descend, either by sliding, rolling, or tumbling down. 6. The centre of gravity in regular uniform and homogeneal bodies, as squares, circles, &c. is the middle point in a line connecting any two opposite points or angles. Wherefore, if such a line is bisected, the point of section will be the centre of gravity. See MECHANICS.

CENTRE *of oscillation*, that point in a pendulum in which, if the weight of the several parts was collected, each vibration would be performed in the same time as when those weights are separate. This is the point whence the length of a pendulum is measured, which, in our latitude, in a pendulum that swings seconds, is 39 inches and 2-10ths. The centre of suspension is the point on which the pendulum hangs.

CENTRE *of percussion*, in a moving body, that point wherein the percutient force is greatest, or that point with which if the body strikes against any obstacle, no shock shall be felt in the point of suspension. See MECHANICS.

CENTRIFUGAL *force*, that force by which all bodies that move round any other body, in a curve, endeavour to fly off from the axis of their motion in a tangent to the periphery of the curve, and that in every point of it. See MECHANICS.

CENTRIPETAL *force*, that force by which a body is every where impelled, or any way tends, toward some point as a centre; such are gravity, or that force whereby bodies tend toward the centre of the earth; see MECHANICS; magnetical attraction, whereby the loadstone draws iron; and that force, whatever it be, whereby the planets are continually drawn back from right lined motions, and made to move in curves.

CENTRISCUS, in ichthyology, a genus of fishes belonging to the order of amphibia nantes. The head gradually ends in a narrow snout, the aperture broad and flat: the belly is carinated, and the belly fins united. There are two species, *viz.*

1. The scutatus, which has its back covered with a smooth bony shell, which ends in a sharp spine, under which is the tail, but the back fins are between the tail and the spine. It is a native of the East Indies.

2. The scolopax, see Plate XXVIII. Nat. Hist. fig. 105. has a rough scabrous body, and a straight extended tail. It has two belly fins, with four rays each, and has no teeth. It is found in the Mediterranean.

CENTRUM *tendinosum*, in anatomy, a point wherein the tendons of the muscles of the diaphragm meet. See ANATOMY.

CENTUMVIRI, in Roman antiquity, judges appointed to decide common causes among the people. They were chosen three out of each tribe; and though five more than a hundred, were nevertheless called centumviri, from the round number centum, a hundred.

CENTUNCULUS, in botany, a genus of plants called by some *anagallidiastrum*, and by others a species of *anagallis*, the characters of which are these: it belongs to the tetrandria monogynia class of plants; the flower is monopetalous, the tube being globose, and the limb divided into four oval segments: the fruit is an unilocular capsule, containing a great number of roundish seeds. There is one species, annual.

CENTURION, among the Romans, an officer in the infantry, who commanded a century or a hundred men. The centurions held the first rank in the first cohort of a legion, and two of them the place of the two first hastati, or pikemen: the first among the principes was also a centurion.

CENTUSSIS, in Roman antiquity, a coin containing a hundred asses.

CEPHALANTHUS, a genus of the tetrandria monogynia class of plants; the corolla consists of a single petal; the tube is slender; the limb is divided into four parts, acute, reflex, and of the length of the tube; the fruit is an oblong capsule, containing only one cell; several of these grow together, and form a roundish head: the seeds are numerous and oblong. There are five species, trees and shrubs of China.

CEPHALIC *medicines*, are remedies for disorders of the head. See MEDICINE.

CEPHALIC *vein*. See ANATOMY.

CEPHEUS, in astronomy, a constellation of the northern hemisphere, the stars of which, in Ptolemy's catalogue, are 13; in Tycho's, 11; in Hevelius's, 40; and in Mr. Flamsteed's, 35.

CEPI *corpus*, in law, a return made by the sheriff, that, upon a capias, or other like process, he has taken the defendant's body.

CERAMBYX, in zoology, a genus of beetles, of the coleoptera order, the characters of which are these: the antennæ are long and setaceous, and the thorax is oblong, rounded, and mucronated or pointed at each extremity. Under this genus is comprehended the capricorn beetle. There are 33 species of this genus enumerated by Linnæus, principally distinguished by the figure of the breast. See Plate XXVII. Nat. Hist. figs. 99 and 100.

CERASTIUM, mouse ear, a genus of the decandria pentagynia class of plants, the flower of which consists of five bifid petals; and its fruit is a very long unilocular pod, containing numerous roundish seeds. There are 18 species of this weed.

CERATE, in pharmacy, a medicine used externally in several diseases, especially those of the skin. It is generally of four sorts, the white cerate, the yellow cerate, the cicatrizing cerate, and the mercurial cerate. See PHARMACY.

CERATIOLA ericoides, heath hornbush, in botany, a plant of the class dioecia, order diandria, cal. none, cor. none, drupa 2 sperm. frutescent, a native of Georgia and Carolina. (*b*)

CERATOCARPUS, a genus of the monoecia monandria class of plants, distinguished by having no petals, and a small, compressed, and bicornate seed, not unlike that of bidens.

CERATONIA, the carob tree, or St. John's bread, a genus of the trioecia order, in the polygamia class of plants, and in the natural method ranking under the 33d order,

lomentaceæ. The calyx is hermaphrodite and quinquepartite; there is no corolla; the stamina are five; the style is filiform; the legumen coriaceous and polyspermous. It is also dioecious, or male and female distinct on different plants. There is but one species, *viz.*

Ceratonia siliqua, a native of Spain, of some parts of Italy, and the Levant. It is an evergreen; and, in the countries where it is native, grows in the hedges. It produces a quantity of long, flat, brown coloured pods, which are thick, mealy, and of a sweetish taste. These pods are eaten by the poorer sort of inhabitants when there is a scarcity of other food; but they are apt to loosen the belly, and cause gripings of the bowels.

CERATOPHYLLUM, a genus of the polyandria order, in the monoecia class of plants, and in the natural method ranking under the 15th order, inundatæ. The male calyx is multipartite; no corolla; stamina from 16 to 20; the female calyx is multipartite; no corolla; one pistil; no style; one naked seed. There are two species, of no note.

CERBERA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 30th order, contortæ. The fruit is a monospermous plum. Of 5, the most remarkable species is,

Cerbera atrouai, a native of the warm parts of America. It rises with an irregular stem to eight or ten feet, sending out many crooked diffused branches, with thick succulent leaves of a lucid green, smooth, and very full of a milky juice. The flowers come out in loose bunches at the end of the branches; they are of a cream colour, having long narrow tubes, and at the top are cut into five obtuse segments, which seem twisted. The wood of this tree smells most abominably, and the kernels of the nuts are a deadly poison, to which there is no antidote; so that the Indians will not even use the wood for fuel.

CERCELE, in heraldry. A cross cercele is a cross which, opening at the ends, turns round both ways like a ram's horn.

CERCIS, the Judas tree, a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 33d order, lomentaceæ. The calyx is quinquedentated, and gibbous below; the corolla papilionaceous, with a short vexillum or flag petal under the wings or side petals; a leguminous plant. There are only two species, both deciduous. The most remarkable is,

Cercis Canadensis, or Canadian cercis; it will grow to the size of twenty feet in some places. The branches are also irregular: the flowers are usually of a palish red, and show themselves in spring, before the leaves are grown to their size. The flowers are often eaten in sallads, and afford an excellent pickle.

CERDONIANS, in church history, persons who maintained most of the errors of Simon Magus, Saturnel, and other Gnostics. They asserted two principles, the one good, and the other evil: this last, according to them, was creator of the world, and the God that appeared under the old law; the first, whom they called unknown, was the father of Jesus Christ; who, they taught, was only incarnate in appearance, and was not born of a virgin, nor suffered death, but in appearance.

CEREALIA, in antiquity, feasts of Ceres, instituted by Triptolemus of Eleusis, in Attica.

CEREBELLUM, in anatomy, the hinder part of the brain. See Anatomy.

CEREBRUM. See Anatomy.

CERINTHE, honey wort, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 41st order, asperifoliæ. The limb of the corolla is a ventricose tube, with the throat pervious; and there are two bilocular seeds. There are two species, natives of Germany, Italy, and the Alps. They are low annual plants, with purple, yellow, and red flowers, which may be propagated by seed sown in autumn, in a warm situation.

CERINTHIANS, in church history, a Christian sect, followers of Cerinthus, who lived and published his heresy in the time of the apostles themselves. They did not allow that God was the author of the creatures, but said that the world was created by an inferior power: they attributed to this creator an only son, but born in time, and different from the world: they admitted several angels and inferior powers; they maintained that the law and the prophets came not from God, but from the angels; and that the God of the Jews was only an angel. They distinguished between Jesus and Christ: and said, that Jesus was a mere man, born, like other men, of Joseph and Mary; but that he excelled all other men in prudence and wisdom; that Jesus being baptized, the Christ of the supreme God, that is, the Holy Ghost, descended upon him; and that by the assistance of this Christ, Jesus performed his miracles. It was partly to refute this sect that St. John wrote his Gospel.

CEROPEGIA, in botany, a genus of the pentandria monogynia class. The flower consists of a single petal; the tube is cylindraceous, oblong, and terminating with a long globose base; the limb is small, and divided into five segments: the fruit is two cylindraceous acuminated floscules, containing one cell, and divided by two valves; the seeds are numerous, imbricated, and oblong. There are six species.

CERTHIA, in ornithology, the creeper or ox eye, a genus belonging to the order of picæ. The beak is arched, slender, sharp, and triangular; the tongue is sharp at the point; and the feet are of the walking kind, or having the toes open and unconnected. Of this genus near 50 species have been enumerated. The following are a few of the most remarkable:

1. The familiaris, or common ox eye, is gray above and white underneath, with brown wings, and ten white spots on the ten prime feathers. This bird is found in most parts of Europe, though it is believed no where so common as in Britain. It may be thought more scarce than it really is by the less attentive observer; for, supposing it on the body or branch of any tree, the moment it observes any one, it gets to the opposite side, and so on, let a person walk round the tree ever so often. The facility of its running on the bark of a tree, in all directions, is wonderful; this it does with as much ease as a fly on a glass window. Its food is principally, if not wholly, insects, which it finds in the chinks and among the moss of trees. It builds its nest in some hole of a tree, and lays generally five eggs, very rarely more than seven: these are ash coloured, marked at the end with spots and streaks of a deeper colour.

2. The hook billed green creeper inhabits the Sandwich islands in general, and is one of the birds whose plumage the natives make use of in constructing their feathered garments; which having these olive green feathers, intermixed with the beautiful scarlet and yellow ones belonging to the next species, and yellow tufted bee eater, make some of the most beautiful coverings of these islanders.

3. The pusila, or brown and white creeper, is not above half the size of our European creeper. The upper part of the body is brown, with a changeable gloss of copper: the under parts are white. It is a native of the Cape, and is fond of honey.

4. The Loteni, or Lotens creeper, has the head, neck, back, rump, scapulars, and upper tail coverts, of green gold; beneath, from the breast to the vent, of velvet black, which is separated from the green on the neck by a transverse bright violet band. It inhabits Ceylon and Madagascar.

5. The cerulea, or blue creeper, has the head of a most elegant blue; but on each side there is a stripe of black like velvet, in which the eye is placed: the chin and throat are marked with black in the same manner; the rest of the body violet blue. It inhabits Cayenne. It makes its nest with great art. The outside is composed of dry stalks of grass, or such like; but within of very downy soft materials, in the shape of a retort, which it suspends from some weak twig, at the end of a branch of a tree, the opening or mouth downward, facing the ground: the neck is a foot in length, but the real nest is quite at the top, so that the bird has to climb up this funnel like opening to get at the nest. Thus it is secure from every harm; neither monkey, snake, nor lizard, daring to venture at the end of the branch, as it would not steadily support them.

6. The sannio, or mocking creeper, is of the size of the lesser thrush. On the cheeks is a narrow white spot: the head, especially on the crown, is inclined to violet; the plumage in general is olive green. It inhabits both the islands of New Zealand. It has an agreeable note in general; but at times so varies and modulates the voice, that it seems to imitate the notes of all other birds; hence it was called by the English the mocking bird. See Plate XXVII. Nat. Hist. fig. 101.

CERTIFICATE, in law, a writing made in any court, to give notice to another court of any thing done therein. The clerks of the crown, assize, and the peace, are to make certificates into the king's bench of the tenor of all indictments, convictions, outlawries, &c.

CERTIFICATION *of assize of novel disseisin*, a writ granted for the re-examination or review of a matter passed by assize before any justices; as where a man appearing by his bailiff to an assize brought by another, has lost the day, and having something more to plead for himself, as a deed of release, &c. which the bailiff did not or might not plead for him, desires a further examination of the cause, either before the same justices or others, and obtains letters patent to that effect.

CERTIORARI. The writ of certiorari is an original writ, issuing out of the court of chancery or the king's bench, directed in the king's name to the judges or officers of inferior courts, commanding them to certify or to return the records of a cause depending before them, to the end the party may have the more sure and speedy justice before the king or such justices as he shall assign to determine the cause. 1 Bac. Abr.

A certiorari lies in all judicial proceedings in which a writ of error does not lie; and it is a consequence of all inferior jurisdictions erected by act of parliament, to have their proceedings returnable in the king's bench. Ld. Raym. 469.

In particular cases the court will use their discretion to grant a certiorari, as if the defendant is of good character, or if the prosecution is malicious, or attended with oppressive circumstances. Leach's Ham. 2. c. 27. s. 28. n.

The courts of chancery and king's bench may award a certiorari; to remove the proceeding from any inferior courts, whether they are of ancient or newly created jurisdiction, unless the statute or charter which creates them exempts them from such jurisdiction. 1 Salk. 144. pl. 3.

CERT MONEY, a fine paid yearly by the residents of several manors to the lord thereof, and sometimes to the hundred, *pro certo lete*, that is, for the certain keeping of the leet.

CERVICAL *nerves*. See Anatomy.

CERVIX, in anatomy, denotes properly the hinder part of the neck. See Anatomy.

CERUSE, or Ceruss, white lead, a sort of calx of lead, made by exposing plates of that metal to the vapour of vinegar. See Chymistry.

CERVUS, the stag or deer kind, in zoology, a genus of quadrupeds of the order of the pecora. The generic character is: horns solid, covered while young with a hairy skin, growing from the top, naked, annual, branched. Front teeth in the lower jaw, eight. Canine teeth, none; sometimes single in the upper jaw.

1. Cervus alces, or elk. The elk, by far the largest animal of this genus, is, when full grown, scarcely inferior to a horse in size. It is common to both continents, inhabiting only the coldest regions, and is observed to arrive at a greater magnitude in Asia and America than in Europe. In its shape it is much less elegant than the rest of the deer tribe; having a very short and thick neck, a large head, horns dilating almost immediately from the base into a broad palmated form, a thick, broad, heavy upper lip, hanging very much over the lower; very high shoulders, and long legs. Notwithstanding its awkward proportions, it is, however, of a noble and majestic appearance. It is also a mild and harmless animal, and principally supports itself by browsing the boughs of trees in the vast and dreary forests of the frozen zone. The greatest height of the elk is about seventeen hands, and its greatest weight about 1229 pounds. The horns have been known to measure each 32 inches in length. The female is rather smaller than the male, and has no horns. See Plate XXVIII. Nat. Hist. fig. 103.

In Europe the elk is found chiefly in Sweden, Norway, and some parts of Russia. In Asia it occurs in the woody tracts of the Russian dominions; and in Siberia in particular is found of gigantic magnitude. In America it seems to be most common in Canada, and the country round the great lakes, and is called by the name of moose deer.

The elk, though naturally of an inoffensive and peaceable disposition, displays a high degree of courage, and

even ferocity, when suddenly attacked; defending himself with great vigour, not only with his horns, but also by striking violently with his fore feet, in the use of which he is so dexterous as easily to kill a dog, or even a wolf, at a single blow.

2. Cervus tarandus, or reindeer, see Plate XXVIII. Nat. Hist. fig. 104. like the elk, is an inhabitant of the northern regions. In Europe its chief residence is in Norway and Lapland. In Asia it frequents the north coast as far as Kamtschatka, and the inland parts as far as Siberia. In America it occurs in Greenland, and does not extend further south than Canada. The height of a full grown reindeer is four feet six inches: the body is of a somewhat thick and square form, and the legs shorter in proportion than those of the stag. Its general colour is brown above and white beneath; but as it advances in age, it often becomes of a grayish white. No animal of this tribe appears to vary so much in the form and length of its horns as the reindeer. In general the horns are remarkable for their great length and proportional slenderness, and are furnished with a pair of brow antlers, with widely expanded and palmated tips directed forward. In the young and middle aged reindeer the horns are remarkable for their slender form; but as the animal advances in age, they are of a stronger appearance. With the Laplanders, indeed, this animal is at once the substitute of the horse, the cow, the sheep, and goat.

3. Cervus elaphus, or stag, is one of those innocent and peaceable animals that seem destined to embellish the forest, and animate the solitudes of nature. The elegance of his form, the lightness of his motions, the strength of his limbs, and the branching horns with which his head is decorated, conspire to give him a high rank among quadrupeds, and to render him worthy the admiration of mankind. It varies both in size and colour in different countries, but is generally about three feet and a half high, and of a reddish brown colour, whitish beneath. The horns vary as to size, &c. The general number of branches in a well grown stag seems to be six or seven, but they are sometimes far more numerous.

The stag is a native of almost all the temperate parts of Europe, as well as of Asia. It also occurs in North America, where it occasionally arrives at a larger size than in the old continent, except in Siberia, where it is found of gigantic magnitude.

Stags in general cast or shed their horns sooner or later in the month of March, in proportion to their ages. At the end of June they are full grown, and the animal rubs them strongly against the boughs of trees, or any convenient object, in order to free them from the skin, which is now become useless, and by the beginning of August they assume the full strength and consistence, which they retain throughout the remainder of the year.

4. Cervus dama, or fallow deer, is considerably smaller than the stag, and is of a brownish bay colour, more or less deep in different individuals; whitish beneath, on the insides of the limbs, and beneath the tail, which is somewhat longer in proportion than that of the stag. In its general form, the animal greatly resembles the stag, having the same elegance of aspect, with a more gentle disposition. It is not so common as the stag, and is even a rare animal in some parts of Europe, as in France and Germany, but in Spain is said to be found nearly equal to the stag in size. The manners of the fallow deer resemble those of the stag, but it is observed to be less delicate in the choice of its food; eating a variety of vegetables which are refused by the former. It arrives at full growth and perfection in about three years, and is said to live about twenty.

The horns are annually shed, as in the stag, but at a somewhat later period.

5. Cervus Virginianus, Virginian deer, is a native of the northern parts of America, where it is found in vast herds, and is an animal of great importance to the Indian natives, who dry its flesh for their winter provision. The size of the animal is that of the fallow deer: its colour a light cinereous brown; the horns slender, bending very much forward, with numerous branches on the interior sides, and no brow antlers.

This species appears to occur in almost all parts of North America, and they abound in the greatest abundance in the vast savannas contiguous to the Missisippi and the great rivers which flow into it; grazing in innumerable herds, along with stags and buffaloes.

6. Cervus axis, or spotted axis, see Plate XXVIII. Nat. Hist. fig. 102. is a most beautiful animal. Its size is nearly that of the fallow deer, and its colour an elegant light rufous brown, distinctly and beautifully marked with very numerous white spots. It is described by Pliny among the animals of India, and is said to have been sacred to Bacchus. It has been introduced into Europe, and is occasionally seen in parks and menageries. It is readily tamed, and seems to suffer but little from a change of climate.

7. C. Axis, middle. Whether this is a variety of the former, or specifically distinct, does not appear perfectly clear. It is of a middle size, between the spotted axis and the great axis. In the colour of its hair, it resembles the first sort, but is never spotted. It inhabits dry hilly forests in Ceylon, Borneo, Celebes, and Java, where it is found in very numerous herds. Its flesh is much esteemed by the natives, and is dried and salted for use.

8. C. Axis, great. The existence of this species or variety is ascertained from a pair of horns in the British museum, resembling the former kinds in shape, but of larger size: they measure two feet nine inches in length, are of a whitish colour, and are very strong, thick, and rugged. Mr. Pennant conjectures that they were brought from Ceylon or Borneo, having been informed by Mr. Loten, who had long resided in the former of these islands, that a very large kind of stag, as tall as a horse, of a reddish colour, and with trifurcated horns, existed there as well as in Borneo.

9. Cervus pygargus, or tailless roe. This species is described in the first volume of Dr. Pallas's Travels, and is a native of the mountainous parts of Hircania, Russia, and Siberia; inhabiting the loftiest parts of those regions, but in winter descending into the plains, the hair at that season assuming a hoary appearance. In its form it resembles the roebuck, but is larger. Its colour is brown, with the outsides of the limbs and under parts of the body yellowish. It has no tail, but a mere broadish cutaneous excrescence.

10. Cervus Mexicanus, or Mexican roe, is about the size of the common or European roebuck, and of a red-

dish colour, but when young is often spotted with white. The horns are thick, strong, and rugged: they bend forward, and are about ten inches long. The flesh is said to be far inferior to the venison of Europe.

11. Cervus porcinus, porcine deer, has slender trifurcated horns, thirteen inches long and six inches at the base: the height from the shoulders to the hoof is two feet two inches, and about two inches higher behind; the body is thick and clumsy, the legs fine and slender; the colour on the upper part of the neck, body, and sides, is brown; the belly and rump lighter.

12. The cervus capreolus, or common roe, is of a reddish brown colour, and is the smallest of the European animals of this genus.

The common or general measure of the roe is three feet nine inches from nose to tail; the height before, two feet three inches; but behind, two feet seven inches; the horns are about six or eight inches long, and are strong, upright, rugged, and trifurcated: the general colour of the animal is reddish brown, more or less deep in different individuals, and the rump is white. It is an inhabitant of most parts of Europe, as far as Norway; it also occurs in some parts of Asia, but is not to be found in Africa. Whether it is a native of America seems somewhat doubtful, though some species nearly allied to it are found in that continent.

13. Cervus muntjac, or ribbed faced deer, is a native of Java and Ceylon, and is somewhat smaller than the common roebuck, and of a thick form, like the porcine deer. The horns are trifurcated; but what seems principally to distinguish this animal, is the appearance of three longitudinal subcutaneous ribs, extending from the horns to the eyes. From each side of the upper jaw hangs a tusk; so that this species differs in that respect from most of the genus.

14. Cervus guineensis, or gray deer, is the size of a cat; the colour gray, with a line of black between the ears, a large spot of black above the eyes, and on each side of the throat a line of black, pointing downward: the middle of the breast black; the fore legs and sides of the belly, as far as the hams, marked with black; the ears rather long; the under side of the tail black. It is said to be a native of Guinea.

CESARE, among logicians, one of the modes of the second figure of syllogisms; the minor proposition of which is an universal affirmative, and the other two universal negatives: thus,

CE No immoral books ought to be read:
SA But every obscene book is immoral;
RE Therefore no obscene book ought to be read.

CESSATION, cessatio a divinis, in the Romish church, is when, for any notorious injury to the church, a stop is put to all divine offices and the administration of the sacraments, and Christians are deprived of church burial. A cessation differs from an interdict in this, that, during the latter, divine service may be performed in such churches of any place interdicted, as are not expressly under the interdict, and even celebrated solemnly on certain high festivals, the church doors being shut: but in a cessation, no religious service can be performed solemnly; the only liberty allowed is, in order to renew the consecrated hosts, to repeat every week a private mass in the parish churches, the doors being shut, observing also not to ring the bell. Moreover it is lawful, during the cessation, to administer baptism, confirmation, and penance, to such persons as desire it, provided they are not excommunicated, or under an interdict.

CESSAVIT, in law, a writ that lies, in many cases, upon this general ground; that he against whom it is brought has for two years ceased or neglected to perform such service, or to pay such rent, as he is bound to by his tenure, and has not upon his lands and tenements sufficient goods or cattle to be distrained.

CESSION, is where an ecclesiastical person is created a bishop, or where a parson of a parsonage takes another benefice, without dispensation, or otherwise not qualified, &c. in both cases, their first benefices are said to be void by cession: and to those benefices which the person who was created a bishop enjoyed, the king shall present for that time, whosoever is patron of them; and in the other cases the patron may present.

CESTRUM, bastard jasmine, a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 28th order, luridæ. The corolla is funnel shaped; the stamina each sending out a little tooth about the middle of the inside. There are six species, all natives of the warmest parts of America; so cannot be preserved in this country without artificial heat. They are flowering shrubs, rising in height from five to twelve feet, with flowers of a white, or pale yellow colour. The flowers of one species, called Badmington jasmine, emit a strong scent after sunset. They may be propagated either by seed or cuttings.

CESTUI, a French word, signifying he or him, frequently used in our law writings. Thus, cestui qui trust, a person who has lands, &c. committed to him for the benefit of another: and if such person does not perform his trust, he is compellable to it in chancery. Cestui qui vit, one for whose life any lands, &c. are granted. Cestui qui use, a person to whose use any one is infeoffed of lands or tenements. Formerly the feoffees to uses were deemed owners of the land, but now the possession is adjudged in cestui qui use.

CETUS, in astronomy, a constellation of the southern hemisphere, comprehending twenty-two stars in Ptolemy's catalogue, twenty-one in Tycho's, and in the Britannic catalogue ninety-seven.

In this constellation is a variable star which appears and disappears periodically, passing through the several degrees of magnitude both increasing and diminishing in about 333 days.

CETE, the seventh order in the mammalia class of animals; the characters of which are, breathing apertures on the head, tail horizontal, no claws. The animals of this order are all of the whale kind.

Nature has bestowed on this tribe an internal structure in all respects agreeing with that of quadrupeds; and in a few others the external parts are both similar. Cetaceous fish, like land animals, breathe by means of lungs, being destitute of gills. This obliges them to rise frequently on the surface of the water to respire, to sleep on the surface, as well as to perform several other functions. They have the power of uttering sounds, such as bellowing and making other noises denied to genuine fish. Like land animals they have warm blood, bring forth, and suckle

their young, showing a strong attachment to them. Their bodies beneath the skin are entirely surrounded with a thick layer of fat, blubber, analogous to the lard on hogs. The number of their fins never exceeds three, *viz.* two pectoral fins, and one back fin; but in some species the last is wanting. Their tails are placed horizontally, or flat, in respect to their bodies; contrary to the direction of those of all other fish, which have them in a perpendicular site. This situation of the tail enables them to force themselves suddenly to the surface of the water to breathe, which they are so frequently constrained to do. Notwithstanding the many parts and properties which cetaceous fish have in common with land animals, yet there still remain others which render it more natural to place them in the rank of fish: the form of their bodies agrees with that of fish; they are entirely naked, or covered only with a smooth skin; they live constantly in the water, and have all the actions of fish. This order comprehends the monodon, or narwhale, or sea unicorn; balæna, or common whale; the physeter, cachalot, or spermaceti whale; and delphinus, dolphin, grampus, porpus, &c.

CHA, in commerce, a thin light silk stuff made in China, and worn by the inhabitants for a summer dress.

CHÆROPHYLLUM, chervil: a genus of the digynia order, in the pentandria class of plants; and in the natural method ranking under the 45th order, umbellatæ. The involucrum is reflexed concave, the petals inflexed cordate; the fruit oblong and smooth. There are ten species, two of which, called cow weed and wild chervil, are weeds common in many places in Britain. The roots of the first have been found poisonous when used as parsneps; the flowers afford an indifferent yellow dye; the leaves and stalks a beautiful green. Its presence indicates a fertile soil, but it ought to be rooted out from all pastures early in the spring, as no animal but the ass will eat it. The leaves are recommended by Geoffroy as aperient and diuretic, and at the same time grateful to the palate and stomach. He even asserts that dropsies which do not yield to this medicine can scarcely be cured by any other. He directs the juice to be given in the dose of three or four ounces every fourth hour, and continued for some time, either alone or in conjunction with nitre and syrup of the five opening roots. The other species of chærophyllum are not possessed of any remarkable property.

CHÆTODON, in ichthyology, a genus of fishes belonging to the order of thoracici. The teeth are very numerous, thick, setaceous, and flexile; the rays of the gills are six. The back fin and the fin at the anus are fleshy and squamous. There are 23 species, distinguished from each other principally by the figure of the tail, and the number of spines in the back fin. The most remarkable is the acuminatus, or shooting fish, having a hollow cylindrical beak. It is a native of the East Indies, where it frequents the sides of the sea and rivers in search of food; from its singular manner of obtaining which it receives its name. When it spies a fly sitting on the plants that grow in shallow water, it swims to the distance of four, five, or six feet; and then, with a surprising dexterity, it ejects out of its tubular mouth a single drop of water, which never fails striking the fly into the water, where it soon becomes its prey. See Plates XXVIII. and XXXIII. Nat. Hist. figs. 113, 114, 115, 116.

CHAFFERS, in our old records, signify wares or merchandise; and hence the word chaffering is used for buying and selling.

CHAIN, a kind of measure in France, in the trade of wood for fuel: there are chains for wood by tale, for wood by the rope, for faggots, for cleft wood, and for round sticks: there are also chains measuring the sheaves of all sorts of corn, &c.

CHAINS *in a ship*, those irons to which the shrouds by the masts are made fast to the chain walls, which are the broad timbers made jetting out of the sides, to which the shrouds are fastened and spread out, the better to secure the masts.

CHAIN SHOT, two bullets with a chain between them. They are used at sea to shoot down yards or masts, and to cut the shrouds or rigging of a ship.

CHAIN PUMP. See PUMP.

CHAIN, in surveying, a measure of length, made of a certain number of links of iron wire, serving to take the distance between two or more places. Gunter's chain contains 100 such links, each measuring $7\frac{92}{100}$ inches, and consequently equal to 66 feet, or four poles. See SURVEYING.

CHALCEDONY, in natural history, a genus of semipellucid gems, of an even and regular not tabulated texture, of a semi-opaque crystaline basis, and variegated with different colours, dispersed in form of mists and clouds, and, if nicely examined, found to be owing to an admixture of various kinds of earths or metals, but imperfectly blended in the mass, and often visible in distinct moleculæ. Of this genus there are a great many species, as the blnish white chalcedony; the brownish black chalcedony, or smoky jasper or capnitis of the ancients; and the yellow and red chalcedony.

This stone is found abundantly in many countries, particularly in Iceland and the Ferro islands. It is most commonly amorphous, or in rounded masses. Its specific gravity is from 2.615 to 2.703; and it is composed of 84 parts of silica, and 16 of alumina, mixed with iron. When striped white and black, or brown alternately, it is called *onyx;* when striped white and gray, it is denominated *chalcedonix*. Black or brown chalcedony, when between the eye and a strong light, appears of a dark red.

CHALDRON, a dry English measure, consisting of thirty-six bushels, heaped up according to the sealed bushel kept at Guildhall, London; but on ship board, twenty-one chaldron of coals are allowed to the score. The chaldron should weigh two thousand pounds.

CHALIZA, in Hebrew antiquity, the ceremony whereby a woman, left a widow, pulled off her brother in law's shoes, who should have espoused her; after which she was at liberty to marry whom she pleased.

CHALK, in natural history, the English name of the white, dry, calcareous earth, with a dusty surface, found in hard masses, and called by authors creta, and terra creta. See CHYMISTRY.

CHALLENGE, taken either against persons or things: persons, as in assize the jurors, or any one or more of them; or in a case of felony, by a prisoner at the bar.

Challenge of jurors is of two kinds; either to the array, by which is meant the whole jury as it stands arrayed in the pannel or little square pane of parchment on which

the jurors' names are written; or to the polls, by which are meant the several particular persons or heads in the array. 1 Inst. 156.

Challenge to the array is in respect of the partiality or default of the sheriff, coroner, or other officer that made the return; and it is then twofold: 1st. Principal challenge to the array, which if it is made good, is a sufficient cause of exception, without leaving any thing to the judgment of the triers; as if the sheriff is of kindred to either party; or if any of the jurors are returned at the denomination of either of the parties. 2d. Challenge to the array for favour, which being no principal challenge must be left to the discretion and conscience of the triers; as where either of the parties suspects that the juror is inclined to favour the opposite party. 1 Inst. 158.

Principal challenge to the polls, is where cause is shown, which if found true, stands sufficient of itself, without leaving any thing to the triers; as if the juror is under the age of twenty-one, it is a good cause of challenge.

Challenge to the polls for favour, is when neither party can take any principal challenge; but shows causes of favour, as that the juror is a fellow servant with either party.

In cases of high treason, and misprision of high treason, the prisoner shall have his peremptory challenge to the number of thirty-five. 1 Inst. 156. But with regard to petit treason, murder, and other felonies, the 22 Hen. VIII. c. 14. continues in force, which takes away the peremptory challenge of more than twenty.

CHAMA, in zoology, a genus of shell fish belonging to the order of testacea. The shell is thick and has two valves: there are 14 species, principally distinguished by the figure of the shells. See Plate XXVIII. Nat. Hist. figs. 107, 108.

There is a great variety among the several species of chama; some being perfectly smooth, some striated, and some rugose, or even spinose; whilst others are oblong, others roundish; and some are equilateral. Among the species of this genus, we may reckon the concha Veneris, or Venus's shell, with a spinose edge; the agate chama; and the chama gryphoides and cordata.

CHAMÆROPS, the dwarf palm, or little palmetto, a genus of the natural order of palmæ. The hermaphrodite calyx is tripartite; the corolla tripetalous; there are six stamina, three pistils, and three monospermous plums. The male is a distinct plant, the same as the hermaphrodite. There are three species, the most remarkable of which is the

Chamærops glabra, a native of the West Indies, and warm parts of America, also of the corresponding latitudes of Asia and Africa. It never rises with a tall stem; but when the plants are old, their leaves are five or six feet long, and upward of two broad; these spread open like a fan, having many foldings, and at the top are deeply divided like the fingers of a hand. This plant the Americans call thatch, from the use to which the leaves are applied. It may be easily raised in this country from seeds brought from America; but as the plants are tender, they must be constantly kept in a bark stove.

CHAMBER, in policy, the place where certain assemblies are held, also the assemblies themselves. Of these some are established for the administration of justice, others for commercial affairs.

Of the first kind are, 1. star chamber, so called, because the roof was painted with stars; the authority, power, and jurisdiction of which, are absolutely abolished by the statute 17 Car. 1. 2. Imperial chamber of Spire, the supreme court of judicatory in the empire, erected by Maximilian I. This chamber has a right of judging by appeal, and is the last resort of all civil affairs of the states and subjects of the empire, in the same manner as the aulic council of Vienna. Nevertheless it is restrained in several cases; it takes no notice of matrimonial causes, these being left to the pope; nor of criminal causes, which either belong to particular princes or towns in their respective territories, or are cognisable by all the states of the empire in a diet. By the treaty of Osnaburgh in 1648, fifty assessors were appointed for this chamber, whereof twenty-four were to be protestants, and twenty-six catholics, besides five presidents, two of them protestants, and the rest catholics. 3. Apostolical chamber of Rome, that wherein affairs relating to the revenues of the church and the pope are transacted. This council consists of the cardinal camerlingo, the governor of the rota, a treasurer, an auditor, a president, one advocate general, a solicitor general, a commissary, and twelve clerks. 4. Chamber of London, an apartment in Guildhall, where the city money is deposited. Of the last sort are, 1. The chambers of commerce. 2. The chambers of assurance.

The chamber of commerce is an assembly of merchants and traders, where the affairs relating to trade are treated of. There are several established in most of the chief cities of France; and in our own country, we have lately seen chambers of this kind erected for various purposes. Chamber of assurance in France, denotes a society of merchants and others for carrying on the business of insuring; but in Holland, it signifies a court of justice, where causes relating to insurances are tried.

CHAMBERLAIN, an officer charged with the management and direction of a chamber.

Chamberlain. The office of lord great chamberlain of England is hereditary; and where a person dies seized in fee of this office, leaving two sisters, the office belongs to both, and they may execute it by deputy, but such deputy must be approved of by the king, and must not be of a degree inferior to a knight. To the lord chamberlain the keys of Westminster hall, and the court of requests, are delivered upon all solemn occasions. He disposes of the sword of state to be carried before the king, when he comes to the parliament, and goes on the right hand of the sword next the king's person. He has the care of providing all things in the house of lords in the time of parliament. To him belong livery and lodgings in the king's court, &c. and the gentleman usher of the black rod, yeoman usher, &c. are under his authority.

The lord chamberlain of the household has also superintendence of artificers retained in the king's service, messengers, comedians, revels, music, &c.

Chamberlain of London is commonly the receiver of all rents and revenues belonging to that city, and has great authority in making and determining the rights of freemen, and regulating matters concerning apprentices, orphans, &c.

Chamberlain of Chester, when there is no prince of Wales and earl of Chester, receives and returns all writs coming thither out of any of the king's courts.

CHAMBRANLE, among builders, an ornament of stone or wood bordering the three sides of doors, windows, and chimnies.

CHAMFER, or CHAMFRET, in architecture, an ornament consisting of half a scotia, being a kind of a small furrow or gutter on a column, called also scapus, stria, &c.

CHAMPAIN, or POINT CHAMPAIN, in heraldry, a mark of dishonour in the coat of arms of him who kills a prisoner of war after he has cried quarter.

CHAMPARTY, or CHAMPERTY, is the unlawful maintenance of a suit, in consideration of some bargain to have part of the lands or thing in dispute, or part of the gain. By stat. 33 Ed. I. st. 3. both the champartor, and he who consents thereunto, shall be imprisoned three years, and make fine at the king's pleasure.

CHAMPION, a person who undertook a combat in the place or quarrel of another; and sometimes the word is used for him who fought in his own cause. It appears that champions, in the just sense of the word, were persons who fought instead of those that, by custom, were obliged to accept the duel, but had a just excuse for dispensing with it, as being too old, infirm, or being ecclesiastics, and the like. Such causes as could not be decided by the course of common law were often tried by single combat; and he who had the good fortune to conquer, was always reputed to have justice on his side. Champions who fought for interest only where held infamous; these hired themselves to the nobility, to fight for them in case of need, and did homage for their pension. When two champions were chosen to maintain a cause, it was always required that there should be a decree of the judge to authorize the combat: when the judge had pronounced sentence, the accused threw a gage or pledge, originally a glove or gauntlet, which being taken up by the accuser, they were both taken into safe custody till the day of battle appointed by the judge. Before the champions took the field, their heads were shaven to a kind of crown or round, which was left at the top; then they made an oath that they believed the person who retained them, to be in the right, &c. They always engaged on foot, and with no other weapon than a club and a shield, which weapons were blessed in the field by the priest, with great ceremony; and they always made an offering to the church, that God might assist them in the battle. The action began with railing, and giving each other ill language; and at the sound of a trumpet, they went to blows. After the number of blows or encounters expressed in the cartel, the judges of the combat threw a rod into the air, to advertise the champions that the combat was ended. If it lasted till night, or ended with equal advantage on both sides, the accused was reputed the victor. If the conquered champion fought in the cause of a woman, and it was a capital offence, the woman was burnt, and the champion hanged. If it was the champion of a man, and the crime capital, the vanquished was immediately disarmed, led out of the field, and hanged, together with the party whose cause he maintained. If the crime was not capital, he not only made satisfaction, but had his right hand cut off: the accused was to be close confined in prison, till the battle was over.

CHAMPION *of the king*, a person whose office it is, at the coronation of our kings, to ride armed into Westminster hall, while the king is at dinner there, and, by the proclamation of a herald, make challenge to this effect, *viz.* "that if any man shall deny the king's title to the crown, he is there ready to defend it in single combat," &c. which being done, the king drinks to him; and sends him a gilt cup, with a cover, full of wine, which the champion drinks, and has the cup for his fee.

CHANCE, is more particularly used for the probability of an event; and is greater or less, according to the number of chances by which it may happen, compared with the number of chances by which it may either happen or fail. Thus, if an event has three chances to happen, and two to fail, the probability of its happening may be estimated $\frac{3}{5}$, and the probability of its failing $\frac{2}{5}$. Therefore, if the probabilities of happening and failing are added together, the sum will always be equal to unity.

If the probabilities of happening and failing are unequal, there is what is commonly called odds for, or against, the happening or failing, which odds are proportional to the number of chances for happening or failing.

The expectation of obtaining any thing, is estimated by the value of that thing, multiplied by the probability of obtaining it. The risk of losing any thing, is estimated by the value of that thing, multiplied by the probability of losing it. If, from the expectations which the gamesters have upon the whole sum deposited, the particular sums they deposite, that is, their own stakes, are subtracted, there will remain the gain, if the difference is positive; or the loss, if the difference is negative. Again, if from the respective expectations which either gamester has upon the sum deposited by his adversary, the risk of losing what he himself deposites is subtracted, there will likewise remain his gain or loss.

If there is a certain number of chances by which the possession of a sum can be secured, and also a certain number of chances by which it may be lost, that sum may be ensured for that part of it, which shall be to the whole, as the number of chances there are to lose it, is to the number of all the chances.

If two events have no dependence on each other, so that p be the number of chances by which the first may happen, and q the number of chances by which it may fail; and likewise, that r be the number of chances by which the second may happen, and s the number of chances by which it may fail: multiply $p + q$ by $r + s$, and the product $pr + qr + ps + qs$ will contain all the chances by which the happening or failing of the events may be varied amongst one another.

From what has been said, it follows, that if a fraction expresses the probability of an event, and another fraction the probability of another event, and these two events are independent, the probability that these two events will happen, will be the product of the two fractions.

Ex. 1. Suppose a person playing with a single die offers to wager, that he will throw an ace each time for two successive throws; what probability has he of succeeding?

SOLUTION. Suppose the wager 36*l.* and that, on throwing the first time, an ace did come up; then, because there are six faces on the die, only one of which is right, his expectation on the second throw will be $\frac{1}{6}$th of 36*l.* or $\frac{36}{6} = 6l.$ But the probability of this event being also $\frac{1}{6}$th, the expectation, before the first throw must necessarily be $\frac{1}{6}$th of 6*l.* or 1*l.* Therefore the probability of his losing the wager will be $1 - \frac{1}{6} \times \frac{1}{6} = 1 - \frac{1}{36} = \frac{35}{36}$, from

which it appears that no person ought to hazard such a wager, unless the value of 35 to 1 shall be laid against him.

Ex. 2. A person offers to lay a wager of 1*l.* that out of a purse containing $m + n$ counters, of which m are black, and n white, he will, blindfolded, at the first trial, draw a white counter; and also that, out of another purse containing M and N counters, of which M are black, and N white, he will also, blindfolded, at the first trial, draw a white counter; and that, if he fail in either trial, his wager shall be lost. What probability is there that he shall succeed?

Solution. If, as in the last example, he had already succeeded in the first trial, it would follow that his expectation on the second will be $\frac{N}{M+N}$: but if the success of the first trial be a condition of obtaining this expectation, then the probability of so doing will be $\frac{n}{m+n}$; which multiplied into that expectation, will give $\frac{n}{m+n} \times \frac{N}{M+N}$, or $\frac{Nn}{m+n \times M \times N}$, for the probability required.

Hence the probability of the happening of two *independent* events, will be equal to the product of the probabilities of their happening separately. Of course, if the two events are of the same kind, then the probability will be $\frac{n^2}{\overline{m+n}^2} = \frac{n^2}{m^2+2mn+n^2}$. More generally:

I. Let the number of chances for the happening of an event be a, and the number of chances for its failing be b; then the probability of its happening once in any number of trials will be expressed by the series $\frac{a}{a+b} + \frac{ab}{\overline{a+b}^2} + \frac{ab^2}{\overline{a+b}^3} + \frac{ab^3}{\overline{a+b}^4} + \frac{ab^4}{\overline{a+b}^5} + \frac{ab^5}{\overline{a+b}^6}$, &c. continued to as many terms as are equal to the number of trials given. Thus, if $a = 1$, $b = 5$, and the number of trials be 1, 2, 3, 4, 5, &c. then the probability will be $\frac{1}{6}$ for one trial; $\frac{1}{6} + \frac{5}{36} = \frac{11}{36}$ for two trials; $\frac{1}{6} + \frac{5}{36} + \frac{25}{216} = \frac{91}{216}$ for three trials, and so on.

II. Things remaining as before, the probability of the event's happening *twice* in any given number of trials, will be expressed by the following series, continued to as many terms, *wanting one*, as the number of trials given: $\frac{a^2}{\overline{a+b}^2} + \frac{2a^2b}{\overline{a+b}^3} + \frac{3a^2b^2}{\overline{a+b}^4} + \frac{4a^2b^3}{\overline{a+b}^5} + \frac{5a^2b^4}{\overline{a+b}^6}$, &c. $= \frac{1}{36} + \frac{10}{216} + \frac{75}{1296} + \frac{500}{7776} + \frac{3125}{46656}$. These being summed up, we have for two trials $\frac{1}{36}$; for three trials $\frac{16}{216}$; for four $\frac{171}{1296}$; for five $\frac{1526}{7776}$; for six $\frac{12281}{46636}$, &c.

III. The probability of the event's happening *three* times in any number of trials, will be expressed by the series $\frac{a^3}{\overline{a+b}^3} + \frac{3a^3b}{\overline{a+b}^4} + \frac{6a^3b^2}{\overline{a+b}^5} + \frac{10a^3b^3}{\overline{a+b}^6}$, which is to be continued to as many terms, wanting two, as is the number of terms given: thus a and b as before, $\frac{1}{216} + \frac{15}{1296} + \frac{150}{7776} + \frac{1250}{46656}$, which being summed up for three trials $= \frac{1}{216}$, for four $= \frac{21}{1296}$, for five $= \frac{276}{7776}$, &c.

Generally a = chances for happening,
b = ditto for failing,
l = number of times for producing the event in a given number of trials,
n = number of trials,
$a + b = s$; then the following series is universal:

$$\frac{a^l}{s^l} \times 1 + \frac{lb}{s} + \frac{l.l+1.b^2}{1.2.s^2} + \frac{l.l+1.l+2.b^3}{1.2.3.s^3} + \frac{l.l+1.l+2.l+3.b^4}{1.2.3.4.s^4}.$$

For when $l = 1$, the series will be

$\frac{a}{a+b} + \frac{ab}{\overline{a+b}^2}$, &c. as in the first case;

$l = 2$, the series will be

$\frac{a^2}{\overline{a+b}^2} + \frac{2a^2b}{\overline{a+b}^3}$, &c. as in the second case;

$l = 3$, the series will be

$\frac{a^3}{\overline{a+b}^3} + \frac{3a^3b}{\overline{a+b}^4}$, &c. as in the third case; and so on universally.

Remark. The above series must be continued to so many terms exclusive of the common multiplicator $\frac{a^l}{s^l}$, as are denoted by the number $n - l + 1$.

And, for the same reason, the probability of the contrary, that is, of the event's not happening so often as l times, making $n - l + 1 = p$, will be expressed by the series $\frac{b^p}{sp} \times 1 + \frac{pa}{s} + \frac{p.p+1.aa}{1.2.ss} + \frac{p.p+1.p+2.a^3}{1.2.3.s^3}$, which series is to be continued to so many terms, exclusive of the common multiplicator, as are denoted by the number l.

Either series may be used, according as l is less or greater than $\frac{n+1}{2}$. It is to be observed of these series, that they are both derived from the same principle: for,

supposing two adversaries, A and B, contending about the happening of that event, which has every time a chances to happen, and b chances to fail; that the chances a are favourable to A, and the chances b to B, and that A should lay a wager with B that his chances should come up l times in n trials; then, by reason B lays a wager to the contrary, he himself undertakes that his own chances shall, in the same number of trials, come up $n - l + 1$ times; and therefore if in the first series, we change l into $n - l + 1$, and *vice versa;* and also write b for a, and a for b; the second series will be formed. See Nature and Laws of Chance, by Thomas Simpson; Demoivre on chances; Dodson's Mathematical Repository, vol. ii. p. 32, &c.

CHANCE MEDLEY, in law, is the accidental killing of a man, not wholly without the killer's fault; it is also called manslaughter by misadventure, for which the offender shall have his pardon of course, 6 Ed. I. c. 9. But here is to be considered, whether the person who commits this manslaughter by chance medley was doing a lawful thing; for if the act was unlawful it is felony. Chance medley is properly applied to such killing as happens for self defence in a sudden rencounter. 4 Blacks. 183.

CHANCEL, a particular part of the fabric of a Christian church; it is the rector's freehold and part of his glebe, and therefore he is obliged to repair it; but where the rectory is impropriate, the impropriator must do it.

CHANCELLOR, an officer supposed originally to have been a notary or scribe under the emperors; and named cancellarius, because he sat behind a lattice, called in Latin cancellus, to avoid being crowded by the people. The chancellor originally presided over a political college of secretaries, for the writing of treaties, and other public business; and the court of equity, under the old constitution, was held before the king and his council, in the palace, where one supreme court for business of every kind was kept. At first the chancellor became a judge, to hear and determine petitions to the king, which were preferred to him; and in the end, as business increased, the people addressed their suit to the chancellor, and not to the king; and thus the chancellor's equitable power by degrees, commenced by prescription.

Lord high chancellor of Great Britain, or lord keeper of the great seal, is the highest honour of the long robe; being made so per traditionem magni sigilli per dominum regem, and by taking the oaths: he is the first person of the realm next after the king, and princes of the blood, in all civil affairs; and is the chief administrator of justice next the sovereign, being the judge of the court of chancery, which is styled a court of equity. This equity consists in abating the rigour of the common law, and giving a remedy in cases where no provision, or not sufficient provision, had been made by the ordinary course of law. The jurisdiction of this court is of vast extent. Almost all causes of weight and moment, first or last, have their determination here. In this court relief is given in the case of infants, married women, and others not capable of acting for themselves. All frauds for which there is no remedy at law are cognisable here; as also all breaches of trust, and unreasonable or unconscionable engagements. It will compel men to perform their agreements; will remove mortgagers and obligors against penalties and forfeiture, on payment of principal, interest, and costs; will rectify mistakes in conveyances; will grant injunctions to stay waste; and restrain the proceedings of inferior courts, that they exceed not their authority and jurisdiction. 3 Blacks. 48. This court will not retain a suit for any thing under 10*l.* value, except in cases of charity, nor for lands under 40*s.* per annum.

The lord chancellor not only keeps the king's great seal, but also all patents, commissions, warrants, &c. from the king, are, before they are signed, perused by him: he has the disposition of all ecclesiastical benefices in the gift of the crown under 20*l.* a year, in the king's books; and he is speaker of the house of lords.

CHANCELLOR *of a cathedral*, an officer that hears lessons and lectures read in the church, either by himself or his vicar; to correct and set right the reader when he reads amiss; to inspect schools; to hear causes; apply the seal; write and despatch the letters of the chapter; keep the books; take care that there are frequent preachings, both in the church and out of it; and assign the office of preaching to whom he pleases.

CHANCELLOR *of a diocese*, a lay officer under a bishop, who is judge of his court.

CHANCELLOR *of the dutchy of Lancaster*, an officer appointed chiefly to determine controversies between the king and his tenants of the dutchy land, and otherwise to direct all the king's affairs belonging to that court.

CHANCELLOR *of the exchequer*, an officer who presides in that court, and takes care of the interest of the crown. He is always in commission with the lord treasurer, for the letting of crown lands, &c. and has power with others, to compound for forfeitures of lands, upon penal statutes: he has also great authority in managing the royal revenues, and national finances.

CHANCELLOR *of the order of the garter, and other military orders*, is an officer who seals the commissions and mandates of the chapter and assembly of the knights, keeps the register of their proceedings, and delivers acts thereof under the seal of their order.

CHANCELLOR *of an university*, is he who seals the diplomas, or letters of degrees, provision, &c. given in the university.

The chancellor of Oxford is usually one of the prime nobility, chosen by the members of the university in convocation. He is their chief magistrate: his office is durante vita, to govern the university, preserve and defend its rights and privileges, convoke assemblies, and do justice among the members under his jurisdiction. Under the chancellor is the vice chancellor, who is chosen annually, being nominated by the chancellor, and elected by the university in convocation: he is always the head of some college, and in holy orders. His proper office is to execute the chancellor's power, to govern the university according to her statutes, to see that officers and students do their duty, that courts be duly called, &c. When he enters upon his office, he chooses four pro vice chancellors out of the heads of the colleges, to execute his power in his absence.

The chancellor of Cambridge is also usually one of the prime nobility, and in most respects the same as that of Oxford, only he does not hold his office durante vita, but may be elected every three years. Under the chancellor there is a commissary, who holds a court of record for all privileged persons and scholars under the degree of master

of arts, where all causes are tried and determined by the civil and statute law, and by the custom of the university. The vice-chancellor of Cambridge is chosen annually, by the senate, out of two persons nominated by the heads of the several colleges and hall.

CHANCERY, apostolic, a court in the church of Rome, belonging to the pope. The pope's datory and chancery courts were formerly one and the same thing: but the multitude of affairs to be transacted therein, obliged him to divide it into two tribunals, which are so nearly related to one another, that the chancery does no more than dispatch all that has passed through the datory court. The officers belonging to this court are the regent, prelates, and registers. There are also six masters in chancery, whose business it is to collect the bulls: each of these employments is purchased for six thousand crowns. These are subordinate to the master of the rolls, who keeps the registers of the bulls.

CHANDELIER, in fortification, a kind of moveable parapet, consisting of a wooden frame, made of two upright stakes, about six feet high, with cross planks between them; serving to support the fascines to cover the pioneers. The chandeliers differ from blinds in this, that the former cover the men only before, whereas the latter cover them also above. They are used in approaches, galleries, and mines, to hinder the workmen from being driven from their stations.

CHANNEL, in architecture, that part of the Ionic capital which is under the abacus.

CHANNEL *of the larmier*, the hollow soffit of a cornice which makes the pendant mouchette.

CHANNEL *of the volute*, in the Ionic capital, the face of the circumvolution inclosed by a listel.

CHANTLATE, in building, a piece of wood fastened near the end of the rafters, and projecting beyond the wall to support two or three rows of tiles, so placed as to prevent the rain-water from trickling down the sides of the walls.

CHAOS, in zoology, a genus of insects belonging to the order of zoophyta. The body has no shell or covering, and is capable of reviving after appearing to be dead for a considerable time. It has no joints, or external organs of sensation. There are five species, mostly obtained by infusions of different vegetables in water, and only discoverable by the microscope.

CHAPEAU, in heraldry, an antient cap of dignity worn by dukes, being scarlet-coloured velvet on the outside, and lined with a fur.

CHAPEL, a place of divine worship, served by an incumbent under the denomination of a chaplain.

In England there are several sorts. 1. Parochial chapels, which, differing from parish churches only in the name, are generally small, as the inhabitants within the district are few. If there is a presentation *ad ecclesiam* instead of *ad capellam*, and an admission and institution upon it, it is no longer a chapel, but a church. 2. Chapels which adjoin to and are part of the church: such were formerly built by honourable persons as burying-places for themselves and their families. 3. Chapels of ease, built in very large parishes for the convenience of such as cannot repair to the parish church. These are served by inferior curates provided at the charge of the rector, and consequently removeable at his pleasure. 4. Free chapels, such as were founded by the kings of England, free from all episcopal jurisdiction, and to be visited only by the founder and his successors: the visitation is made by the lord chancellor. The king likewise may license any subject to build and endow a chapel, and by letters patent exempt it from the visitation of the ordinary. 5. Chapels in universities belonging to particular colleges, which, though consecrated, and though sacraments are administered there, are not liable to the visitation of the bishop. 6. Domestic chapels, built by gentlemen for the private service of God in their own families. These may be erected without the leave of the bishop, and need not be consecrated, though they were anciently: they are not subject to the visitation of the ordinary.

Knights of the CHAPEL, called also poor knights of Windsor, were instituted by Henry VIII. in his testament. Their number was at first thirteen, but has been since augmented to twenty-six. They assist in the funeral services of the kings of England: they are subject to the office of the canons of Windsor, and live on pensions assigned them by the order of the garter. They bear a blue or red cloke, with the arms of St. George on the left shoulder.

CHAPLAIN, an ecclesiastic who officiates in a chapel.

The king of great Britain has forty-eight chaplains in ordinary, who wait four each month, preach in the chapel, read the service to the family, and to the king in his private oratory, and say grace in the absence of the clerk of the closet. Besides, there are twenty-four chaplains at Whitehall, fellows of Oxford or Cambridge, who preach in their turns, and are allowed 30*l. per annum* each. According to a statute of Henry VIII. the persons vested with a power of retaining chaplains, together with the number each is allowed to qualify, is as follows: an archbishop, eight; a duke or bishop, six; marquis or earl, five; viscount, four; baron, knight of the garter, or lord chancellor, three; a duchess, marchioness, countess, baroness, the treasurer and controller of the king's house, clerk of the closet, the king's secretary, dean of the chapel, almoner, and master of the rolls, each of them two; chief justice of the king's bench, and warden of the cinque ports, each one. All these chaplains may purchase a licence or dispensation, and take two benefices with cure of souls. A chaplain must be retained by letters testimonial under hand and seal; for it is not sufficient that he serve as chaplain in the family.

CHAPLET, a string of beads used by the Roman catholics to count the number of their prayers. The invention of it is ascribed to Peter the Hermit, who probably learned it of the Turks, as they owe it to the East Indians. Chaplets are sometimes called pater-nosters, and are made of coral, of diamond, of wood, &c. The common chaplet contains fifty ave-marias and five pater-nosters.

CHAPPE'. in heraldry, the dividing an escutcheon by lines drawn from the centre of the upper edge to the angles below, into three parts, the sections on the sides being of a different metal or colour from the rest.

CHARA, a genus of the monandria order, in the monœcia class of plants. There is neither male calyx nor corolla; and the antheræ is placed under the germen. The female calyx is tetraphylloas; no corolla; the stigma quinquefid, with one roundish seed. There are 4 species.

CHARACTER, in a general sense, denotes any mark

whatever, serving to represent either things or ideas: thus letters are characters, types, or marks, of certain sounds; words, of ideas, &c. See LETTER, &c.

CHARACTER. If one person apply to another for the character of a third person, and a good character as to his solvancy be given, yet if, in consequence of this opinion, the party asking the question suffer loss through the person's insolvency, no action lies against him who gave the character if it were fairly given. 1 Esp. Rep. 442.

But if a man wickedly asserts that which he knows to be false, and thereby draws his neighbour into a loss, it is actionable. 3 T. R, 351. But if the party giving credit also knew that the party credited was in bad circumstances an action will not lie. 1 Esp. Rep. 290.

CHARACTER, a mark or abbreviation used in certain arts and sciences.

CHARACTERS *in Algebra and Arithmetic.*

a, b, c, d, &c. the first letters of the alphabet, are the characters of given quantities; and *z, y, x,* &c. the last letters, are the characters of quantities sought. See ALGEBRA.

m, n, r, s, t, &c. are characters of indeterminate exponents both of ratios and of powers: thus, x^m, y^n, z^r, &c. denote undetermined powers of different kinds; *mx, ny, rz,* different multiples, or submultiples of the quantities *x, y, z,* according as *m, n, r,* are either whole numbers or fractions.

+ is the sign of the real existence of the quantity it stands before, and is called an affirmative or positive sign. It is also the mark of addition, and is read *plus,* or more; thus, *a+b,* or 3+5, implies *a* is added to *b,* or 3 added to 5.

— before a single quantity, is the sign of negation or negative existence, showing the quantity to which it is prefixed to be less than nothing. But between quantities it is the sign of substraction, and is read *minus,* or less; thus, *a—b* or 8—4, implies *b* subtracted from *a,* or 8 after 4 has been subtracted.

= is the sign of equality, though Des Cartes and some others use this mark ∝; thus, *a=b* signifies that *a* is equal to *b.* Wolfius, and some others, use the mark = for the identity of ratios.

× is the sign of multiplication, showing that the quantities on each side the same are to be multiplied by one another, as *a×b* is to be read *a* multiplied into *b;* 4×8, the product of 4 multiplied into 8. Wolfius and others make the sign of multiplication a dot between the two factors; thus 5 . 4 signifies the product of 5 and 4. In algebra the sign is frequently omitted, and the two quantities put together; thus *ba* expresses the product of *b* and *d.* When one or both of the factors are compounded of several letters, they are distinguished by a line drawn over them; thus, the factum of *a+b—c* into *d,* is wrote $d \times \overline{a+b-c}$. Leibnitz, Wolfius, and others, distinguish the compound factors by including them in a parenthesis $(a+b-c)\,d$.

÷ is the sign of division; thus, *a÷b* denotes the quantity *a* to be divided by *b.* In algebra the quotient is often expressed like a fraction, thus $\frac{a}{b}$ denotes the quotient of *a* divided by *b.* Wolfius makes the sign of division two dots; thus 12 : 4 denotes the quotient of 12 divided by 4, =3. If either the divisor or dividend, or both, be composed of several letters, for example *a+b÷c,* instead of writing the quotent like a fraction, $\frac{a+b}{c}$, Wolfius includes the compound quantities in a parenthesis, thus $(a+b) : c$.

⊙ is the character of involution; *v v* is the character of evolution.

⟩ or [‾‾ are signs of majority; thus, *a⟩b* expresses that *a* is greater than *b.*

⟨ or ‾‾] are signs of minority; and when we would denote that *a* is less than *b,* we write *a⟨b,* or *a*‾‾]*b.*

∽ is the character of similitude used by Wolfius, Leibnitz, and others: it is used in other authors for the *difference* between two quantities, while it is unknown which is the greater of the two.

:: is the mark of geometrical proportion disjunct, and is usually placed between two pair of equal ratios, as, 3 : 6 :: 4 : 8, shows that 3 is to 6 as 4 is to 8.

∴ the mark of geometrical proportion continued, implies the ratio to be still carried on without interruption, as 2, 4, 8, 16, 32, 64 ∴ are in the same uninterrupted proportion.

√ is the character of radicality, and shows, according to the index of the power that is set over it, or after it, that the square, cube, or other root, is extracted, or to be extracted; thus, √ 16, or $\sqrt{}^2$ 16, or √ (2) 16, is the square root of 16. $\sqrt[3]{}25$, the cube root of 25, &c. This character sometimes affects several quantities, distinguished by a line drawn over them; thus, $\sqrt{b+d}$ denotes the square root of the sum of *b* and *d.* When any term, or terms, of an equation are wanting, they are generally supplied by one or more asterisks: thus in the equation $y^2+py+\frac{1}{4}p^2+q \left.\begin{matrix} \\ -py-\frac{1}{2}p^2 \end{matrix}\right\} = 0$, the term $\pm py$ vanishing, is marked with an asterism, as $y^2{*}-\frac{1}{4}p^2+q$. See ALGEBRA.

CHARACTERS *used in Astronomy.* See ASTRONOMY.

CHARACTERS *used in the arithmetic of infinities.*

· the character of an infinitesimal or fluxion; thus, $\dot{x}$, $\dot{y}$, &c. express the fluxions or differentials of the variable *x* and *y;* and two, three, or more dots, denote second, third, or higher fluctions. Mr. Leibnitz, instead of a dot, prefixes the letter *d* to the variable quantity, in order to avoid confusion of dots in the differencing of differentials. See CALCULUI DIFFERENTIALIS.

CHARACTERS *in Medicine and Pharmacy.*

℞ recipe	M. manipulus, a handful
á, áá, or ana, of each alike	P. a pugil
℔ a pound or a pint	P. Æ. equal quantities
℥ an ounce	S. A. according to art
ʒ a drachm	q. s. a sufficient quantity
℈ a scruple	q. pl. as much as you please
gr. grains	
ß or *ss,* half of any thing	P. P. pulvis patrum, the jesuits' bark.
cong. congius, a gallon	
coch. cochleare, a spoonful	

CHARACTERS used in Music, and of musical notes, with their proportions, are as follow.

⊏ character of a large	8	□ a breve	2
⊏ a long	4	○ a semibreve	1

minim $\frac{1}{2}$ semiquaver $\frac{1}{16}$

crotchet $\frac{1}{4}$ demisemiquaver $\frac{1}{32}$

quaver $\frac{1}{8}$

♯ character of a sharp note: this character at the beginning of a line, or space, denotes that all the notes in that line are to be taken a semitone higher than in the natural series; and the same affects all the octaves above or below, though not marked: but when prefixed to any particular note, it shows that note alone to be taken a semitone higher than it would be without such character.

♭ or *b*, character of a flat note: this is the contrary to the other above, that is, a semitone lower.

♮ character of a natural note: when in a line or series of artificial notes, marked at the beginning ♭ or ♯, the natural note happens to be required, it is denoted by this character.

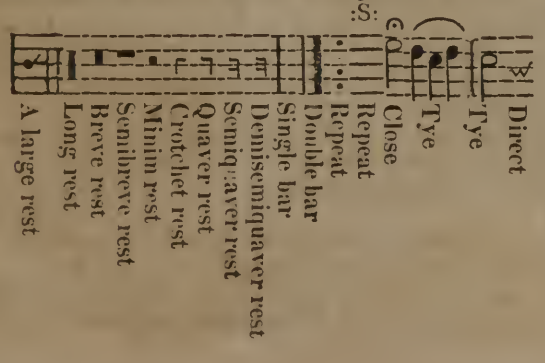
𝄞 character of the treble cliff.

𝄡 character of the mean cliff.

𝄢 bass cliff.

𝄴, or $\frac{2}{4}$, or $\frac{4}{8}$, character of common duple time; signifying the measure of two crotchets to be equal to two notes, of which four make a semibreve.

C 𝄵 characters that distinguish the movements of common time; the first implying slow, the second quick, and the third very quick.



$\frac{1}{2}$, $\frac{3}{2}$, $\frac{3}{4}$, $\frac{3}{8}$, $\frac{3}{16}$, characters of simple triple time, the measure of which is equal to three semibreves, or to three minims.

$\frac{6}{4}$, or $\frac{6}{8}$, or $\frac{6}{16}$, characters of mixed triple time, where the measure is equal to six crotchets, or six quavers.

$\frac{9}{4}$, or $\frac{9}{8}$, or $\frac{9}{16}$, $\frac{9}{1}$, ro $\frac{9}{2}$, characters of compound triple time.

$\frac{12}{4}$, $\frac{12}{8}$, or $\frac{12}{16}$, or $\frac{12}{1}$, or $\frac{12}{2}$, characters of that species of triple time called the measure of twelve times. See TRIPLE.

Characters of the rests or pauses of time.

NUMERAL CHARACTERS used to express numbers, are either letters or figures. The Arabic character, called also the common one, because it is used almost throughout Europe in all sorts of calculations, consists of these ten digits, 1, 2, 3, 4, 5, 6, 7, 8, 9, 0. See ARITHMETIC.

The Greeks had three ways of expressing numbers: first, every letter, according to its place in the alphabet, denoted a number, from α, one, to ω, twenty-four. 2. The alphabet was divided into eight units, α one, β two, γ three, &c. into eight tens, ι ten, κ twenty, λ thirty, &c. and eight hundreds, ϱ one hundred, σ two hundred, τ three hundred, &c. 3. I stood for one, Π (πεντε) five, Δ (δεκα) ten, H (Ἑκαϑον) a hundred, X (χιλια) a thousand, M (μυρια) ten thousand; and when the letter Π inclosed any of these, except I, it showed the inclosed letter to be five times its value; as |Δ| fifty, |H| five hundred, |X| five thousand, |M| fifty thousand.

The Hebrew numerals consisted of their alphabet divided into nine units; thus, א one, ב two, &c.: nine tens; thus, י ten, כ twenty, &c.: nine hundreds; thus, ק one hundred, ר two hundred, &c. and ך five hundred, ם six hundred, ן seven hundred, ף eight hundred, ץ nine hundred. They expressed thousands by the word אלף, with the other numerals prefixed to signify the number of thousands: thus, אלפים two thousand, נאלפים three thousand, &c.

CHARADRIUS, in ornithology, a genus belonging to the order of grallæ. The beak is cylindrical and blunt; the nostrials are linear; and the feet have each three toes. Among the species, of which their are 27 or 28, are,

1. The Alexandrinus, or Alexandrian dottrel, is of a brownish colour, with the forehead, collar, and belly, white; the prime tail-feathers on both sides are white; and the legs are black. It is about the size of a lark, and lives upon insects.

2. The Ægyptius has a black streak on the breast, white eye-brows, the prime tail-feathers streaked with black at the points, and bluish legs. It is found in the plains of Egypt, and feeds on insects.—3. The morinellus has an iron-coloured breast, a small white streak on the breast and eye-brows, and black legs. It is found in Cambridgeshire, Lincolnshire, and Derbyshire. On Lincoln-heath, and on the moors of Derbyshire, they are migratory; appearing there in small flocks of eight or ten only in the latter end of April, and staying there all May and part of June, during which time they are very fat, and much esteemed for their delicate flavour. In the months of April and September they are taken on the Wiltshire and Berkshire downs.

4. The pluvialis (see Plate XXVIII. Nat. Hist. fig. 106) is black above, with green spots, white underneath, and the feet are ash-coloured. It is the green plover of Ray, and is a native of Europe. They lay four eggs, sharply pointed at the lesser end, of a dirty white colour, and irregularly marked, especially at the thicker end, with blotches and spots. They make a shrill whistling noise; and may be enticed within shot by a skilful imitator of their note.

5. The œdicnemus, or stone curlew of Ray, is of a grey colour, with two of the prime wing-feathers black, but white in the middle: it has a sharp bill, and ash-coloured feet; and is about the size of a crow. In Hampshire, Nor-

folk, and on Lincoln-heath, it is called the curlew, from a similarity of colours to the curlew. It breeds in some places in rabbit-burrows; also among stones on the bare ground, laying two eggs of a copper-colour spotted with a darker red. The younger run soon after they are hatched. These birds feed in the night on worms and caterpillars: they will also eat toads, and catch mice. They inhabit fallow lands and downs; and prefer dry places, being never seen in any waters. When they fly, they extend their legs straight out behind; are very shy birds: run far before they take to wing; and often squat: are generally seen single, and are esteemed very delicate food.

CHARAG, the tribute which the Christians and Jews pay to the grand signior. It is generally a pistole a head, and sometimes four crowns. The christians who come to travel in Turkey pay it at the first town they arrive at: others begin to pay it at nine or sixteen years old; but women, priests, rabbis, and religious, are exempted.

CHARCOAL, according to modern chemistry, is an oxide of carbon. When charcoal, however, is prepared in the usual way, by exposing wood in close vessels to a red heat, it always contains a portion of hydrogen; for if a quantity of this charcoal is exposed to a strong heat in a retort of porcelain, iron, or coated glass, a great quantity of gas is obtained. The gas which comes over first is a mixture of carbonic acid and carbureted hydrogen; but the proportion of carbonic acid diminishes, and at last it ceases to come over at all; yet the carbureted hydrogen continues as copious as ever.

The evolution of these gases was long ascribed by chemists to the water which charcoal usually contains, and which it is known to absorb from the atmosphere with considerable avidity. If that was the case, the proportion of carbureted hydrogen ought to diminish at the same rate with the carbonic acid; the hydrogen of the one being equally derived from the decomposition of water with the oxygen of the other. But as the evolution of carbureted hydrogen continues after that of carbonic acid has ceased, it is scarcely possible to deny, that the hydrogen which thus escapes constituted a component part of the charcoal.

If, therefore, we consider the experiments of Morvean on the combustion of the diamond as decisive, we must conclude, that common charcoal is composed of three ingredients, namely, carbon, hydrogen, and oxygen; and it is of course a triple compound.

CHARGE, in gunnery. The mode of charging is too well known to require description. It is only to be noted, that if the ball is red-hot, a tompion, or trencher of green wood, is to be driven in before it. The weight of the powder necessary for a charge is commonly one-half or one-third the weight of the ball, or still less; and indeed, in most cases of service, the quantity of powder used is too great for the intended execution. In the British navy, the allowance for 32-pounders is 7-16ths of the weight of the ball. But it is probable, that if the powder in all ship-guns was reduced to one-third of the weight of the ball, or even less, it would be a considerable advantage, not noly by saving ammunition, but by keeping the guns cooler and quieter, and at the same time more effectually injuring the vessels of the enemy. With the present allowance of powder, the guns are heated, and their tackle and furniture strained, and all this only to render the ball less efficacious: for a ball which can but just pass through a piece of timber, and in the passage looses almost all its motion, is found to rend and fracture it much more than when it passes through with a much greater velocity. See Robins's Tracts, vol. i. Again, the same author observes, that the charge is not to be determined by the greatest velocity that may be produced, but that it should be such a quantity of powder as will produce the least velocity necessary for the purpose in view; and if the windage be moderate, no field-piece should ever be loaded with more than one-sixth, or at the utmost one-fifth, of the weight of its ball in powder; nor should the charge of any bettering-piece exceed one-third of the weight of its bullet. Ibid. Different charges of powder, with the same weight of ball, produce different velocities in the ball, which are in the same subduplicate ratio of the weights of powder; and when the weight of of powder is the same, and the ball varied, the velocity produced is in the reciprocal subduplicate ratio of the weight of the ball; which is agreeable both to theory and practice. See Philos. Trans. 1778, and Hutton's Tracts, vol. i.

But this is on a supposition that the gun is of an indefinite length; whereas, on account of the limited length of guns, there is some variation from this law in practice as well as in theory; in consequence of which it appears that the velocity of the ball increases with the charge only to a certain point, which is peculiar to each gun, where the velocity is the greatest; and that by farther increasing the charge, the velocity gradually diminishes, till the bore is quite full of powder. By an easy fluxionary process, calling the length of the bore of the gun b, the length of the charge producing the greatest velocity ought to be $\frac{b}{2.718281828}$, or about $\frac{3}{4}$ of the length of the bore; where 2.718281828 is the number whose hyp. log. is 1. But, for several reasons, in practice the length of the charge producing the greatest velocity falls short of that above mentioned, and the more so as the gun is longer. From many experiments it is found, that the charge producing the greatest velocity, in guns of various lengths of bore, from 15 to 40 calibers, is as follows:

Length of bore in calibers.	Length of charge for greatest veloc.
15	$\frac{3}{3\,0}$
20	$\frac{3}{1\,2}$
30	$\frac{3}{1\,6}$
40	$\frac{3}{2\,6}$

CHARGE, in heraldry, is applied to the figures represented on the escutcheon, by which the bearers are distinguished from one another; and it is to be observed, that too many charges are not so honourable as fewer.

CHARGE and DISCHARGE. A charge is a thing that binds him who does it, or that which is his, to the performance thereof; and discharge is the removal of that charge. In all cases where an executory thing is created by deed, there, by consent of all the parties, it may by deed be defeated and discharged.

CHARITABLE USES: lands given to alms, and alienated, may be recovered by the donor. 13 Ed. 1. c. 41. Lands, &c. may be given for the maintenance of houses of correction, or of the poor. 35 Eliz. c. 7. Money giv-

en to put out apprentices, either by parishes, or public charities, to pay no duty. 8 Anne, c. 9.

CHARLES'S-WAIN, in astronomy, seven stars in the constellation called ursa major, or the great bear.

CHART, or *sea-chart*, an hydrographical map, or a porjection of some parts of the earth's superficies in plano, for the use of navigators. Charts differ very considerably from geographical or land maps, which are of no use in navigation. Nor are sea-charts all of the same kind; some being what we call plane charts, others Mercator-charts, and others globular charts.

Plane CHART is a representation of some part of the superficies of the terraqueous globe, in which the meridians are supposed parallel to each other, the parallels of latitude at equal distances, and consequently the degrees of latitude and longitude every where equal to each other. See NAVIGATION.

Mercator's CHART, is that wherein the meridians are straight lines parallel to each other, and equidistant; the parallels are also straight lines, and parallel to each other: but the distance between them increases from the equinoctial towards either pole, in the ratio of the secant of the latitude to the radius.

If the superficies of the terrestrial globe is supposed to be taken off, and extended on a plane, so as to make the meridians parallel to each other, and the degrees of longitude every where equal, it is easy to conceive that it must be productive of the most notorious errors; for an island in latitude 60°, where the radius of the parallel is only equal to one-half of the radius of the equator, will have its length from east to west distorted in a double ratio to what it was on the globe: that is, its length from east to west, in comparison of its breadth from north to south, will be represented in a double proportion to what it really is: whence it follows, that in whatever proportion the degrees of any parallel are increased or diminished by a projection in plano, the degrees of longitude ought to be increased or diminished in the same ratio; for otherwise the true bearings and distances of places will be lost, as in the case of the plane-chart where the degrees of latitude and longitude are all equal.

Though this projection is generally called Mercator's projection, yet our countryman, Mr. Wright, had long before invented it, demonstrated its use, and shown a ready way of constructing it, by enlarging the meridian line, by a continued addition of secants: but neither of these gentlemen is thought the original author of it, having been hinted by Ptolemy about two thousand years ago. See NAVIGATION.

Globular CHART, a meridional projection, wherein the distance of the eye from the plane of the meridian, upon which the projection is made, is supposed to be equal to the sine of the angle of 45°. This projection comes the nearest of all to the nature of the globe, because the meridians therein are placed at equal distances, the parallels also are nearly equidistant, and consequently the several parts of the earth have their proper proportion of magnitude, distance, and situation, nearly the same as on the globe itself.

CHARTA, MAGNA, the great charter of liberties granted first by king John, and afterwards, with some alterations, confirmed in parliament by king Henry the Third. It is so called, either for the excellence of the laws therein contained, or because there was another charter, called the charter of the forests, which was the less of the two; or in regard of the great wars and trouble in obtaining it. King Henry the Third, after it had been several times confirmed by him, and as often broken, at last, in the 37th year of his reign, confirmed it in the most solemn manner in Westminsterhall. Afterwards king Ed. I. confirming this charter, in the 35th year of his reign, made an explanation of the liberties therein granted to the people, adding some; and in the confirmation, he directed that this charter should be read twice a year to the people, and sentence of excommunication to be constantly denounced against all that by word, or deed, or counsel, shall act contrary thereto, or in any degree infringe it.

CHARTER, is a deed whereby the king passes any grant to any one person or more, or to any body politic.

CHARTER-PARTY, is a contract under hand and seal, executed by the freighter and the master and owner of the ship, containing the terms upon which the ship is hired to freight: the masters and owners usually bind themselves, the ship, tackle, and furniture, that the goods freighted shall be delivered (dangers of the sea excepted) well conditioned at the place of discharge; and they also covenant to provide mariners, tackle, &c. and to equip the ship complete and adequate to the voyage. The freighter stipulates to pay the consideration-money for the freight, and penalties are annexed to enforce the reciprocal covenants. A charter-party is the same in the civil law, as an indenture at common law; and is distingoished from a bill of lading, inasmuch as the former adjusts the terms of the freight, and the latter ascertains the contents of the cargo.

CHARTREUSE, or *grande chartreuse*, a celebrated monastery, the capital of all the convents of the Carthusian monks, situated on a steep rock in the middle of a large forest of fir-trees, about seven miles north-east of Grenoble, in the province of Dauphiny, in France. From this mother-convent all the others of the same order take their name; among which was the chartreuse of London, corruptly called the CHARTER-HOUSE, now converted into an hospital, endowed with a revenue of 600*l.* per annum.

Here are maintained eighty decayed gentlemen, not under fifty years of age; also forty boys are educated and fitted either for the university or trades. Those sent to the university, have an exhibition of 20*l.* a year for eight years: and have an immediate title to nine church-livings in the gift of the governors of the hospital who are sixteen in number, all persons of the first distinction, and take their turns in the nomination of pensioners and scholars.

CHACE, a great quantity of ground lying open and privileged for wild beasts and wild fowl. Such is Enfield-chace. A chace differs from a forest, inasmuch as it may be in the hands of a subject, which a forest in its proper nature cannot; and from a park, in that it is not enclosed, and has more officers. A chace is not endowed like a forest with so many liberties, as the courts of attachment, swainmote, and justice-seat; and cannot lawfully be made, without license from the king under the broad seal.

CHATTELS or *catals*, all sorts of goods and pro-

perty moveable or immoveable, except freehold property.

CHAZINZARIANS, in church history, a sect of heretics who adored the cross.

CHECK, or *check roll*, a roll or book, wherein are contained the names of such persons as are attendants and in pay to the king, or other great personages.

Clerk of the CHECK, in the king's household, has the check and control of the yeomen of the guard, and all the ushers belonging to the royal family; allowing their absence or defects in attendance, or diminishing their wages for the same, &c. He also, by himself or deputy, takes the view of those that are to watch in the court, and has the setting of the watch, &c. Clerk of the check in the king's navy at Plymouth, is also the name of an officer invested with the like power.

CHECKS, or *drafts*, on bankers, are instruments by means of which a creditor may assign to a third person, not originally party to the contract, the legal as well as equitable interest in a debt raised by it, so as to vest in such an assignee a right of action against the original debtor. 1 H. B. 602. These instruments are uniformly made payable to bearer, which constitutes a characteristic difference between them and bills of exchange; and the legislature has considered them in a more favourable point of view by exempting them from the stamp-duties. They are equally negotiable with bills, although, strictly speaking, not due before payment is demanded. When given in payment they are considered as cash; and it is said, may be declared upon as a bill of exchange; and the moment this resemblance begins, they are governed by the same principles of law as bills of exchange.

Checks payable on demand, or where no time of payment is expressed, are payable on presentment without any indulgence or days of grace; but the presentment should be made within a reasonable time after the receipt, otherwise the party upon whom the check is drawn, will not be responsible, and the person from whom the holder received it will be discharged. Therefore, where circumstances will allow of it, it is advisable for the holder of the check to present it on the same day it is received.

CHECKY, in heraldry, is when the shield, or a part thereof, as a bordure, &c. is chequered, or divided into chequers or squares, in the manner of a chess-board.

This is one of the most noble and most ancient figures used in armoury.

CHEEKS, among mechanics, are almost all those pieces of their machines and instruments, that are double, and perfectly alike; as the cheeks of a mortar, which are made of strong wooden planks, of a semicircular form, bound with thick plates of iron, and fixed to the bed with four bolts: these cheeks rise on each side of the mortar, and serve to keep it at what elevation is given it: the cheeks of a printing-press are its two principal pieces, placed perpendicular and parallel to each other, and serving to sustain the three sommers, &c.

CHEEKS, in ship-building, two pieces of timber, fitted on each side of the mast, at the top, serving to strengthen the mast there, and having holes in them, called hounds, through which the ties run to hoist the yards. Also the uppermost rail, or piece of timber in the beak of a ship, and these on each side of the trail-board, are called the upper and lower cheek.

The knees also which fasten the beak-head to the bows of the ship, are called cheeks.

CHEIRANTHUS, stock gilliflower, and wall-flower: a genius of the 39th natural order, siliquosæ, and belonging to the tetradynamia class of plants. The germen is marked with a glandulous denticle on each side; the calyx is close, with two of its leaves gibbous at the base; the seeds plane. There are 22 species, of which the following are most worthy of notice.

1. Cheiranthus annuus, or ten weeks stock, with an upright, woody, smooth stalk, divided into a branchy head, twelve or fifteen inches high, with spear-shaped, blunt, hoary leaves, and all the branches terminated by long erect spikes of numerous flowers, of different colours in different varieties.

2. Cheiranthus cheiri, or the common wall-flower, the branches terminating in long erect spikes or numerous flowers, which in different varieties are yellow, bloody, white, &c.

3. Cheiranthus incanus, the hoary cheiranthus, the top of the stalk and all the branches terminated by erect spikes or flowers from one to two or three feet long, of different colours in different varieties. The two last sorts are very hardy evergeen biennials or perennials; but the first, being an annual plant, must be continued by seed sown every year; and even the two last, notwithstanding their being perennial, degenerate so much in their flowers after the first year, that it will be proper also to raise an annual supply of them. The seeds are to be chosen from such flowers as have five, six, or more petals, or from such as grow near to the double ones. When fine doubles of the two last kinds are obtained, they may be multiplied by slips from the old plants.

CHEKAO, a kind of paste, prepared by calcination and trituration from a hard stony substance, and afterwards washing the powder in large quantities of fair water. The Chinese use the chekao in drawing the elegant figures we see in the wholly white china-ware, which they afterwards varnish in the common way. See the article PORCELAIN.

CHELIDONIUM, celandine, horned or prickly poppy: a genus of the monogynia order, in the pentandria class of plants: and in the natural method ranking under the 27th order, rhœadeæ. The carolla is tetrapetalous, the calyx diphyllous, the siliqua unilocular and linear. There are five species. One of them, viz. chelidonium majus, is an article in the materia medica. It grows on old walls, among rubbish, and in waste shady places. The herb is of a blewish green colour; the root of a deep red; and both contain a gold-coloured juice; the smell is disagreeable, the taste somewhat bitterish, very acrid, burning and biting the mouth; the root is the most acrid. The juice takes off warts; cures tetters, ring-worms, and the itch; and, diluted with milk, it consumes opaque white spots on the eye. Horses, cows, goats, and swine, refuse to eat the herb.

CHELONE, in botany, a genus of the angiospermia order, in the didynamia class of plants; and in the natural method ranking under the 40th order, personatæ. The calyx is quinquepartite; the rudiment of a 5th filament among the highest stamina; the capsule bilocular. There are five species, viz.

1. Chelone glabra, 2. chelone hirsuta, 3. chelone penstemon, 4. chelone obliqua, and 5. C. campanulata. They are all natives of North America; and are herbaceous flowery perennials, with upright stalks two feet high, decorated with spear-shaped leaves, and beautiful spikes of monopetalous, ringent flowers, red, rose-coloured, blue, and purple. They flower from Sept. to Nov. and are sometimes succeeded by ripe seeds in this country. They are hardy, and may be propagated by seeds in any soil; but the two first multiply so fast by their creeping roots that the seeds are seldom regarded. The last species is the most beautiful.

CHEMISE, in fortification, the wall with which a bastion, or any other bulwark of earth, is lined for its greater support and strength: or it is the solidity of the wall from the talus to the stone-row.

Fire-CHEMISE, a piece of linen-cloth, steeped in a composition of oil or petrol, camphor, and other combustible matters, used at sea, to set fire to an enemy's vessel.

CHEMISTRY is that branch of science, the object of which is to ascertain the simple substances or elements of bodies, the properties of these, and their action on each other. The methods made use of to obtain this knowledge are analysis and synthesis. Chemistry comprehends almost all the changes in natural objects, with which we are more immediately connected, and in which we have the greatest interest: it is subservient to the various arts of life, and the several branches of manufacture which are carried on in every civilized state. Dyeing, bleaching, tanning, glass-making, the working and composition of metals, &c. are all processes in chemistry. In agriculture chemistry investigates the nature of soils; it explains the phenomena of the growth and nourishment of vegetables, and the nature and action of manures. As a science it is connected with all the phenomena of nature, the causes of rain, snow, hail, dew, wind, and earthquakes: it has been called in to the aid of the culinary arts; and its high importance in medicine has been long and universally acknowledged. Chemistry therefore is highly worthy of our attention, because beyond every other branch of study it increases our knowledge, extends the number of our resources, and is thus calculated to promote our enjoyments, and augment our power over the material world. Besides, no study can give us more exalted ideas of the wisdom and goodness of the great First Cause than this, which exhibits the most astonishing effects frequently produced by the most simple means; and displays to our view the great care which has every where been taken to secure the comfort and happiness of every living creature.

The history of Chemistry.—The word chemistry is said to be of Egyptian origin, and equivalent to our phrase natural philosophy, comprehending all the knowledge of natural objects which the ancients possessed. It afterwards acquired a more limited signification, and was confined to the art of working metals, which was in the highest estimation among the ancients. In the third century it was used in a still more limited sense, signifying the art of making gold and silver. In this sense the science was eagerly cultivated by the Greeks; from them it passed to the Arabians, and by these it was introduced into Europe. Those who professed it assumed the form of a sect, under the name of alchymists, who laid it down as a first principle, that all metals are composed of the same ingredients, or that the substances which compose gold exist in all metals, and are capable of being brought into the pure state; hence the great object of their researches was to discover the means of producing this change, and of converting the baser metals into gold. The substance which possessed this wonderful property was called "the philosopher's stone," the touch of which was to change every thing into gold.

From the eleventh to the fifteenth centuries alchymy was in its most flourishing state. The writers who appeared during that period were numerous; among the most celebrated were Albertus Magnus, Roger Bacon, Arnoldus de Villa Nova, Raymond Lully, and the two Isaacs of Holland. Some of their books are altogether unintelligible; others display great acuteness, and an extensive acquaintance with natural objects. They often reason with great accuracy, though generally from mistaken principles. They all boast that they are in possession of the philosopher's stone, and profess to communicate the method of making it; but their language is enigmatical, and evedently intended not to be understood by any but the adepts in their own mysteries. Their writings and vaunted professions gained implicit credit; and the covetous were filled with the desire of enriching themselves by means of discoveries which they pretended to communicate. This laid the unwary open to the tricks of a set of impostors, who offered to communicate their secret for a suitable but large reward. Thus they contrived to get possession of a sum of money with which they absconded or tired out the patience of their pupils by intolerably tedious, expensive, and ruinous processes.

Chemists had for many ages hinted at the importance of discovering a universal remedy, which should be capable of curing, and even of preventing all deseases; and several of them had asserted, that this remedy was to be found in the philosopher's stone, which not only converted baser metals to gold, but possessed also the most sovereign virtue, was capable of curing all diseases in an instant, and even of prolonging life to an indefinite length, and of conferring on the adepts the gift of immortality on earth. This notion gradually gained ground; and the word chemistry, in consequence, at length acquired a more extensive signification, and implied not only the art of making gold, but the art also of preparing the universal medicine.

About the time that the first of these branches was sinking into discredit, the second, and with it the study of chemistry, acquired an unparalleled degree of celebrity, and attracted the attention of all Europe. This was owing to the appearance of Theophrastus Paracelsus, who was born in 1493, near Zurich in Switzerland; and was, in the 34th year of his age, after a number of whimsical adventures, which had raised his reputation to a great height, appointed by the magistrates of Basil to deliver lectures in their city; he was the first public professor of chemistry in Europe.

The character of this extraordinary man is universally known. That he was an impostor, and boasted of

secrets which he did not possess, cannot be denied; but it must be acknowledged that his talents were great, and that his labours were not entirely useless. He contributed not a little to dethrone Galen and Avicenna, who at that time ruled over medicine with absolute power; and to restore Hippocrates and the patient observers of nature to that chair, from which they ought never to have been expelled. He certainly gave chemistry an eclat which it did not before possess; and this must have induced many of those laborious men who succeeded him to turn their attention to the science. Nor ought we to forget that by carrying his speculations concerning the philosopher's stone, and the universal medicine, to the greatest height of absurdity, and by exemplifying their emptiness and inutility in his own person, he undoubtedly contributed more than any man to their disgrace and subsequent banishment from the science.

Van Helmont, who was born in 1577, may be considered as the last of the alchymists. His death completed the disgrace of the universal medicine. His contemporaries, and those who immediately succeeded him, attended solely to the improvement of chemistry. The chief of them were Agricola, Beguin, Glaser, Erkern, Glauber, Kunckel, Boyle, &c.

The foundation of the alchymistical system being thus shaken, the facts which had been collected soon became a heap of rubbish, and chemistry was left without any fixed principles, and destitute of an object. It was then that a man arose, thoroughly acquainted with the whole of these facts, capable of arranging them, and of perceiving the important purpose to which they might be applied, and able to point out the proper objects to which the researches of chemists ought to be directed. This name was Bucker. He accomplished the arduous task in his work entitled Physica Subterranea, published at Francfort 1669. The publication of this book forms a very important æra in the history of chemistry. It then escaped for ever from the trammels of alchymy, and became the rudiments of the science which we find it at present.

Ernest Stahl, the editor of the Physica Subterranea, adopted, soon after Beecher's death, the theory of his master; but he simplified and improved it so much, that he made it entirely his own; and accordingly it has been always distinguished by the name of the Stahlian theory.

Ever since the days of Stahl, chemistry has been cultivated with ardour in Germany and the North; and the illustrious philosophers of these countries have contributed highly towards its progress and its rapid improvement. The most deservedly celebrated of these are Margraf, Bergman, Scheele, Klaproth, &c.

In France, soon after the establishment of the Academy of Science in 1666, Homberg, Geoffroy, and Lemery, acquired celebrity by their chemical experiments and discoveries; and after the new-modelling of the Academy, chemistry became the peculiar object of a part of that illustrious body. Rouelle, who was made professor of chemistry in Paris about the year 1745, contrived to infuse his own enthusiasm into the whole body of the French literary men; and from that moment chemistry became the fashionable study. Men of eminence appeared every where, discoveries multiplied, the spirit pervaded the whole nation, extended itself over Italy, and appeared even in Spain.

After the death of Boyle, and of some other of the earliest members of the Royal Society, little attention was paid to chemistry in Britain, except by a few individuals. The spirit which Newton had infused for the mathematical sciences was so great, that for many years they drew within their votex almost every man of eminence in Britain. But when Dr. Cullen became professor of chemistry in Edinburgh in 1756, he kindled a flame of enthusiasm among the students, which was soon spread far and wide by the subsequent discoveries of Black, Cavendish, and Priestley; and meeting with the kindred fires which were already burning in France, Germany, Sweden, and Italy, the science of chemistry burst forth at once with unexampled lustre. (See the article AIR.) Hence the rapid progress which it has made during the last forty years, the universal attention which it has excited, and the unexpected light which it has thrown on the arts and manufactures.

As the theory now universally received derived, in a great degree, its origin and support from the discovery of the composition of water (See AIR as above), we shall proceed to state this important point of doctrine.

Water was long considered as an elementary principle; no one had been able to decompose it: but since the experiments of Cavendish, Lavoisier, and others, its true nature has been accurately ascertained; and water may now be decomposed with as much facility as almost any other substance with which we are acquainted. Water is composed of oxygen and hydrogen: it may, by undeniable experiments, be converted into these gases, and by the combustion of them in proper proportions, a quantity of water will be produced equal to the weight of the gases employed; of this we shall proceed to give the requisite proofs by experiments.

Experiment 1. A tube of common glass E F (fig. 18), well annealed, and difficult to be fused, about an inch in diameter, is placed across a furnace CFED, in a position somewhat inclined, and to its upper extremity is adapted a glass retort A, containing a known quantity of distilled water, and resting on a furnace V X. To the lower extremity of the glass tube F, is applied to a worm SS, connected with the double tubulated flask H; and to the other tubulure is adapted a bent glass tube KK, destined to convey the gas to an apparatus proper for determining the quality and quantity of it. When the whole is thus arranged, a fire is to be kindled in the furnace CE, and maintained in such a manner as to bring the glass tube EF to a red-head, but without fusing it: at the same time so much fire is to be maintained in the furnace VX, as to keep the water in the retort A in a continual state of ebullition. In proportion as the water in the retort A assumes the state of vapour by ebullition, it fills the interior part of the tube EF, and expels the atmospheric air, which is evacuated by the worm SS, and the tube KK. The steam of the water is afterwards condensed by cooling in the worm SS, and falls drop by drop, in the state of water, into the tubulated flask H. When the whole of the water in the the retort A is evaporated, and the liquor in the vessels suffered to drain off completely, there is found in the

flask H a quantity of water exactly equal to that which was in the retort A: of course there has been no disengagement of any gas: so that this operation was merely a common distillation, which gave absolutely the same result as if the water had never been brought to a state of incandescence in passing through the glass tube EF.

Exp. 2. Every thing being arranged as in the preceding experiment, 28 grains of charcoal reduced to fragments, and which had been previously exposed for a long time to a white heat in close vessels, were next introduced into the glass tube EF. The operation was then conducted as before, and the water in the retort A kept in a continual state of ebullition till it was totally evaporated. The water in the retort A was distilled, as in the preceding experiment; and being condensed in the worm SS, had fallen, drop by drop, into the flask H; but at the same time there had been disengaged a considerable quantity of gas which escaped through the tube KK, and was collected in a proper apparatus. When the operation was finished, there was found nothing in the tube EF but a few ashes; and the 28 grains of charcoal had totally disappeared.

The gases disengaged were found to weigh altogether 113.7 grains: and there were found two different kinds of gas, viz. 144 cubic inches of carbonic acid gas (211), weighing 100 grains; and 380 cubic inches of a very light gas, weighing 13.7 grains. This last gas took fire on being applied to a lighted body in contact with the air. In examining afterwards the weight of the water which had passed into the flask, it was found less than that in the retort A by 85.7 grains.

In this experiment, therefore, 85.7 grains of water, and 28 grains of charcoal, formed carbonic acid gas equal to 100 grains; and a peculiar gas susceptible of inflammation, equal to 13.7 grains.

Exp. 3. The apparatus being arranged as above, instead of the 28 grains of charcoal, 274 grains of thin shavings of iron, rolled up in a spiral form, were introduced into the tube E F: the tube was then brought to a red heat as before; and in the same manner the whole of the water in the retort A was made to evaporate. In this experiment there was disengaged only one kind of gas which was inflammable: there was obtained of it about 406 cubic inches, weighing 15 grains; and the 274 grains of iron, put into the tube EF, were found to weigh 85 grains above what they did when introduced; and the water first employed was diminished 100.

The volume of these iron shavings was found to be greatly enlarged. The iron was scarcely any longer susceptible of attraction by the magnet; it dissolved without effervescence in acids: in a word, it was in the state of a black oxide, like that which has been burnt in oxygen gas. In this experiment there was a real oxidation of the iron by the water, entirely similar to that effected in the air by the aid of heat: 100 grains of water were decomposed; and of these 100 grains 85 united to the iron, to reduce it to the state of black oxide: these 85 grains, therefore, were oxygen; the remaining 15 grains, combined with caloric, formed an inflammable gas. It thence follows that water is composed of oxygen and the base of inflammable gas, in the proportion of 85 to 15, or of 17 to 3. Water therefore, besides oxygen, which is one of its principles, and which is common to it with a great many other substances, contains another peculiar to itself, and which is its constituent radical. This radical has been called *hydrogen*, that is to say, *the generator of water;* and the combination of this radical with coloric, is distinguished by the name of hydrogen gas. See Air.

This radical then is a new combustible body; that is, a body which has so much affinity for oxygen as to be able to take it from caloric, and to decompose oxygen gas. This combustible body itself has so great an affinity for caloric, that unless engaged in some combination, it is always in the aeriform or gaseous state, at the degree of pressure and temperature in which we live.

If it is true, as has been shown, that water is composed of hydrogen, combined with oxygen, it thence results, that by re-uniting these principles, water ought to be re-formed. This indeed is what takes place, as will be seen by the following experiment:

Exp. 4. Take a wide-mouthed glass balloon, A (fig. 19), capable of containing about four gallons, and cement to its mouth a small plate of copper BC, having above it a cylinder of the same metal. *g* D, pierced with three holes to receive three tubes. The first of these, *h* H, is destined to be connected at its extremity *h*, with an air-pump, in order that the balloon A may be exhausted of air. The second tube, *gg*, communicates by its extremity MM, with a reservoir of oxygen gas, and is destined to convey it into the balloon A. The third tube, D *d*, communicates by the extremity NN, with a reservoir of hydrogen gas: the extremity of this tube terminates in an aperture so small as scarcely to admit a very delicate needle. It is through this aperture that the hydrogen gas contained in the reservoir is to pass into the balloon A. In the next place, the small plate BC is pierced with a fourth hole, into which is inserted with cement a glass tube, through which passes a wire FL, having at its extremity L, a small ball destined to make an electric spark pass between the ball and the extremity *y*, of the tube that conveys the hydrogen gas into the balloon A. The wire FL is moveable in the glass tube, in order that the metallic ball L may be brought nearer to, or removed from, the point *y:* the three other tubes *gg*, H*h*, D*d*, are each furnished with a cock.

That the gases may be conveyed in a very dry state through the tubes which conduct them into the balloon A, and that they may be deprived of water as much as possible, you must put into the swelled parts MM and NN of the tubes, some salts capable of attracting the moisture with great activity, such as acetite of potash, muriate of lime, or nitrate of lime. These salts should be only coarsely pounded, in order that they may not form a mass, and that the gasses may pass freely into the interstices left between the fragments. You must be provided with a sufficient quantity of very pure oxygen gas, and nearly a triple volume of hydrogen gas, equally pure. To obtain it in this state, and free from all mixture, you must extract it from water, decomposed by means of every pure and ductile iron.

When every thing has been thus prepared, adapt to the air-pump the tube *h*H, and exhaust the air in the large balloon A; then fill it with oxygen gas, by means of the tube *gg;* and by a certain degree of pressure,

force the hydrogen gas to pass into the balloon A, through the extremity *y* of the tube *d*D*y*; then kindle this gas by means of an electric spark, and if you renew the quantity of each of these two gases, the combustion may be continued for a long time.

In proportion as the combustion proceeds, water is deposited on the internal surface of the balloon A: the quantity of this water gradually increases, and it unites itself into large drops, which run down the sides of the vessel, and are collected in the bottom of it.

It was by an experiment of this kind that Lavoisier ascertained that 85 parts, by weight, of oxygen, and 15 parts, also by weight, of hydrogen, are required to compose an hundred parts of water.

Hence it is evident that water is not a simple substance; that it is composed of two principles, oxygen and hydrogen; and that its two principles separated from each other, have so great an affinity for caloric, that at the common degree of temperature and pressure they cannot exist but under the gaseous form.

Chemical operations and instruments.—The reduction of solids into powders of different degrees of fineness, by means of *pulverization*, &c. is a necessary preliminary operation previously to their being chemically acted upon. But these processes can never reduce substances into their primary or elementary particles; they do not even destroy the aggregation of bodies; for every particle, after the most accurate trituration, forms a small whole, resembling the original mass from which it was divided. The real chemical operations, on the contrary, such as solution, destroy the aggregation of bodies, and separate their constituent and integrant particles from each other. Brittle substances are reduced to powder by means of hammers, pestles and mortars, stones, and mullers. Pestles and mortars are made either of metal, glass, porcelain, marble, agate, &c. according to the hardness and properties of the bodies to be pounded. Wedgewood's ware affords a most excellent kind of mortar for most purposes, as it is very strong, and not liable to be acted upon by acids. Many bodies cannot be reduced to powder by the foregoing methods: such are fibrous substances, as wood, horns of animals, elastic gum, and metals which flatten under the hammer; for these, files, rasps, knives, and graters, are necessary.

The separation of the finer parts of bodies from the coarser, which may want further pulverization, is performed by means of sifting or washing.

A *sieve* for sifting, generally consists of a cylindrical band of thin wood, or metal, having silk, leather, hair, wire, &c. stretched across it. Sieves are of different degrees of fineness.

Washing is used for procuring powders of an uniform fineness much more accurately than by means of the sieve; but it can only be used for such substances as are not acted upon by the fluid which is used. The powdered substance is mixed with water, or some other convenient fluid: the liquor is allowed to settle for a few moments, and is then decanted off: the coarsest powder remains at the bottom of the vessel, and the finer passes over with the liquor. By repeated decantations in this manner, various sediments are obtained, of different degrees of fineness: the last, or that which remains longest suspended in the liquor, being the finest.

Filtration is a finer species of sifting. It is sifting through the pores of paper, or flannel, or fine linnen or sand, or pounded glass, or porous stones, and the like; but is used only for separating fluids from solids, or gross particles that may happen to be suspended in them, and not chemically combined with the fluids. Thus salt-water cannot be deprived of its salt by filtration; but muddy water will deposit its mud. No solid, even in the form of powder, will pass through the above mentioned filtring substances: hence if water or other fluid, containing sand, insects, mud, &c. is placed in a bag or hollow vessel, made of any of those substances, the sand, &c. will remain on the filtre, and the liquor will pass through, and may be received clear in a vessel under it. Unsized paper is a very convenient substance for making filtres for chemical purposes. It is wrapped up in a conical form, and put into a glass funnel, which serves to strengthen the paper and support the weight of the fluid when poured into it.

Decantation is often substituted instead of filtration, for separating solid particles which are diffused through liquors. These are allowed to settle to the bottom, and the clear fluid is gently poured off. If the sediment is extremely light, and apt to mix again with the fluid, by the slightest motion, a syphon is used for drawing off the clear fluid.

Lixiviation is the separation by means of water, or other fluid, of such substances as are soluble in it, from other substances that are not soluble in it. Thus, if a certain mineral consists of salt and sand, or salt and clay, &c. the given body being broken to powder, is placed in water, which will dissolve the salt, and keep it suspended, whilst the earthy matter falls to the bottom of the vessel, and, by means of filtration, may be separated from the fluid.

Evaporation separates a fluid from a solid, or a more volatile fluid from another which is less volatile.

Simple evaporation is used when the more volatile or fluid substance is not to be preserved. Various degrees of heat are employed for this purpose, according to the nature of the substances. It is performed in vessels of wood, glass, metal, porcelain, &c. Basons made of Wedgewood's ware are very convenient, as they are not apt to break by sudden changes of heat. Small flasks of thin glass also: these are placed either over the naked fire, or in a vessel filled with sand, which is then called a sand-bath. This affords a more regular degree of heat, and renders the vessels less liable to be broken.

When the fluid which is evaporated must be preserved, then the operation is called distillation.

Distillation is evaporating in close vessels, when we wish to separate two fluids of different degrees of volatility, and to preserve the most volatile, or both of them. The substance to be subjected to distillation, is put into some vessel that will resist the action of heat, called a retort, an alembic, or a still; having a beak or neck projecting from it, to which is attached another vessel, to receive the fluid that rises first, which is called the receiver. The vessel that contains the liquor to be distilled is placed upon the fire, or in a sand-bath, or over a lamp; the heat causes the most volatile fluid to raise in the form of vapour, and to pass into the receiver, where it is again condensed by cold. This condensation is sometimes assisted by making the vapour pass

through a tube which is immersed in a vessel containing cold water.

A (fig. 1, Plate XXIX) represents a retort used for distillation. It is a vessel, either of glass or baked earth, for containing the liquid to be distilled. When it has a small neck, *a*, with a stopper fitted to it, for introducing the materials through, it is called a tubulated retort. B is the receiver for condensing the vapour which is raised, and into which the neck of the retort is inserted. The joining, *b*, is made air-tight by means of some substance applied to it, called a lute. Various methods are used for supporting both the retort and receiver, according to the degree of heat employed in the process, and several other circumstances. See LUTE.

When great heat is employed, earthen retorts are used, which are placed on or in the fire. When a less heat is wanted, glass retorts are generally employed; which must not be placed immediately on the fire, unless they are coated over with a composition of clay and sand, which is sometimes done. Glass retorts are generally placed in a sandbath, or suspended over a lamp, for which Argand's lamp is the best. The receiver is placed upon some stand convenient for the purpose, with a ring made of hay under it, or some such contrivance, to keep it steady.

A (fig. 2) is a vessel called a mattrass, for the same purpose, having a vessel, B, called an alembic, fitted to the head. The liquid raised by heat into the state of vapour, is condensed in the alembic, and falls into a groove all round its inside, whence it runs out dy the spout C, into the receiver D.

Fig. 3, are conical tubes that fit into one another, for lengthening the necks of retorts, &c. to connect them with the receivers at any distance: they are called adopters.

Fig. 4, are phials with bent glass tubes fitted in them, for disengaging gases, and similar experiments.

Fig. 5, represents an improved chemical apparatus, such as is used by Mr. Davy in his experiments at the Royal institution. A is a japanned tin vessel, filled within two or three inches of the top with water. Just below the surface of the water is fixed a shelf having several holes bored through it, to which small funnels are attached underneath. The glass receiver B, intended to receive the gas, is filled with water; and being inverted with its mouth under water, it is raised up gently, and placed upon the shelf over one of the holes, where it will remain full of water, which is kept up by the pressure of the atmosphere in the same way as the mercury is retained in the tube of the barometer. The material from which the gas is to be disengaged is put into the retort G, which is put through, and suspended in one of the rings of the lamp furnace D. E is an improved Argand's lamp, having two concentric wicks, placed on the shelf F. The shelf is moveable up and down to bring the lamp to a convenient distance from the retort. The lamp is to be lighted, and as soon as the substances in the retort act upon each other sufficiently, the gas will begin to be disengaged, and will ascend through the hole in the shelf into the vessel F, and displace the water with which it had been filled. When the water is displaced, the receiver is full of gas which was disengaged from the retort, and may be preserved in it by keeping its mouth always under water in the cistern. This gas may be transferred from the vessel B to any other, in the following manner: Fill the vessel into which the gas is to be transferred with the fluid in the trough, and place it on the shelf over one of the holes. Then take the vessel B, and keeping its mouth still under the fluid, bring it under the hole on which the vessel is placed; then depressing its bottom, and elevating its mouth, so as to bring it more to a horizontal position, the gas in it will escape and rise up through the hole on which the other vessel has been placed, and will fill it by displacing the fluid.

If the oxyd of manganese is put into the retort G, and the lamp applied to it, great plenty of oxygen gas will escape from the retort, and will fill the receiver B.

When the gas to be procured is absorbable by water, quicksilver is used instead of water, and a much smaller vessel than A is made use of, which is generally made of wood or stone. A small glass vessel, capable of containing an ounce measure, is used for measuring gases; for if this phial is successively filled and inverted under a large jar, we may thereby throw into that jar any required quantity of an elastic fluid, and as much of another as we please.

G (fig. *5) is a strong glass graduated tube, for receiving a mixture of gases that are to be exploded by the electric spark. Near the closed end two wires pass through the glass, and almost touch each other: they are cemented in, so as to make the holes air-tight. Gases may be introduced into this tube; and if the interval between the two wires is made a part of the electric circuit, by putting chains connected with a Leyden phial to the rings of the wires, the spark will pass through the interrupted space between the two wires, and explode the gases.

A (fig. 6) is a glass retort, the beak of which is adjusted to a double tubulated balloon B. To the upper opening of the balloon is fitted a glass tube C, the other extremity of which is conveyed into the liquor contained in the glass vessel D: with this are connected two or three, or more similar vessels, by means of glass tubes, and to the last tubulure of the range of vessels is adapted a glass tube which is conveyed under a receiver placed upon the shelf of the pneumatic cistern. A (fig. 5.)

Water is poured into the first of these vessels; caustic potash into the next, or such other substances as are necessary for absorbing the gases; and the joinings are well fluted. By this method the purest and most concentrated products are obtained; because the water, which is always the receiver, becomes saturated with them. In this way the common muriatic acid, the oxygenated muriatic acid, volatile alkali, &c. &c. may be made in the best manner.

Large vessels for containing air, and expelling any given quantity, are called gazometers. They are of various constructions; one of the best is the following: A B (fig. 7) is a cylindrical vessel of tin, japanned, nearly filled with water; and having a tube C in the middle, open at top, and branching, to communicate with the cock D. Within this vessel there is another cylindrical vessel, generally of glass, of smaller size, F, open at bottom; which is inverted and suspended by the lines ee, which go over the pulleys f, f, f, f, and have

weights gg, attached to them, to balance the vessel F. While the cock D remains shut, if the vessel F is pressed downwards, the air included within it will remain in the same situation, on the principle of the diving-bell; but if the cock is opened, and the vessel F is pressed down, the air included within it will escape through the cock; and if a blow-pipe is attached to this cock, a stream of the gas may be thrown upon lighted charcoal, or any other body. By means of the graduated rod h, also, the quantity thrown out is exactly ascertained: this rod is so divided as to express the contents of the inner vessel in cubic feet, &c. This instrument also answers for breathing any of the gases, by applying a mouth piece to the cock. To render it more portable, the weights gg are sometimes included in the uprights ii, which are hollow and wide enough to receive them. Sometimes also there is another branch from the bottom of the pipe, in the middle, directed to the side of the other cylinder, and coming upwards by the side to the top, where there is another cock attached.

Crystallization.—When a salt is dissolved in water, or other fluid, and by evaporation the fluid is driven off, the salt gradually acquires the solid form, and in doing this, it arranges its particles in a particular manner; some salts arrange themselves in the form of pyramids, some of prisms of different kinds, &c. Vessels of earthenware, or glass, are employed for such crystallizations. They must be placed where they are perfectly still, and well defended from dust or accidents.

Solution.—When a salt is mixed with water, it loses its state of solidity; the particles of salt are divided and unite themselves to those of the water, forming a liquid, of which all the parts are homogeneous, or of the same kind. The same takes place when resin is mixed with spirits of wine. In this process neither the salt nor the water is decomposed; and the salt may be recovered again in its original state and quantity, by driving off the water by evaporation.

The dissolution of metals by acids, however, is of a different nature: here, either the metal, the acid, or the water, is altered, and different products are obtained. Vessels of glass are generally used for solutions and dissolutions. The liquid used for dissolving a metal, or other solid substance, is usually called a solvent, or menstruum.

Precipitation.—The recovery or separation of a body from its solvent, by the addition of a third substance, so that the former may re-appear in a solid state, however divided, is called precipitation. The substance thus recovered, is called a precipitate, and the superadded body that occasions this precipitation is called a precipitant.

Fusion.—The melting, or causing any body to pass from the solid to the liquid state, by the action of fire, is called fusion. The fusion of metallic substances requires vessels sufficiently strong to resist the fire. These vessels are mostly, if not always, made of earthenware, or porcelain, or a mixture of clay and powder of black-lead. They are called crucibles, and are generally of the forms represented fig. 8; sometimes these vessels have covers made of earthenware; but sometimes the fused metal must be exposed to a current of air. In that case the crucibles are broad and shallow, as at fig. 9. These are called cupels; and they are formed of calcined bones, mixed with a small quantity of clay, or of a mixture of clay and black-lead powder. But the cupels must not be placed in a closed furnace, or be surrounded by coals; for, in that case, the required current of air could not have access to the fused metal. They are therefore placed under a sort of oven of earthenware, which is called a muffle, as represented fig. 10; which, with the included cupel, is exposed to the heat of a furnace.

Furnaces.—In the application of the action of heat to bodies, furnaces of different forms are employed, according to the operations for which they are destined. A furnace is a kind of hollow cylindric tower, A B C D (fig. 11); sometimes a little wider at the top, with notches *m*, *m*, *m*, to give a passage to the air. This furnace ought to have at least two lateral apertures; an upper one F, which is the door of the fire-hole H I; and a lower one G, which is the door of the ash-hole C D. In the interval between these two doors the furnace is divided into two parts by a horizontal grate, destined to support the charcoal. The place occupied by this grate is indicated by the line H I; above the grate is the fire-hole where the fire is maintained; and below it is the ash-hole, where the ashes are collected as they are formed.

Another kind of furnace often necessary, is that called the reverberating furnace (fig. 12); it consists of an ash-hole H I K L, a fire-hole K L M N, a laboratory M N R R, and a dome R R S S; above the dome is a tube T T V V, to which several more can be added if required. In the laboratory is placed a retort, which is supported by two iron bars that run across the furnace; the neck of it passes the lateral aperture O, and has adapted to it a receiver. As a strong heat is sometimes required for the furnace, a large volume of air must be made to pass through it; and in that case a great deal of heat is disengaged. For this reason, instead of one aperture to the ash-hole, there must be two: when only a moderate heat is required, one of them may be shut; if a strong heat is necessary, they may be both opened. It will be of advantage also to make the upper aperture T T of the dome pretty large. The use of the dome is to reverberate the heat and flame on the retort, in order that it may every where be exposed to nearly an equal heat; by which means the vapours can be condensed only in the beak of the retort and in the receiver, and are also forced to proceed thither. When matters which do not require a strong degree of heat are to be fused, the reverberating furnace may be employed as a fusing furnace. The laboratory M N R R in that case is removed; and the dome R R S S is placed on the fire-hole M N, as represented.

One of the best fusing furnaces ever made, is that constructed by Lavoisier, and which is represented fig. 13. The following is the description which he gives of it in his Elements of Chemistry. This furnace is in the form of an elliptical spheroid A B C D, cut off at the two ends by two planes which pass perpendicular to the axis through the foci of the ellipse. From this shape it is capable of containing a considerable quantity of charcoal, while it leaves sufficient space in the intervals for the passage of the air. That no obstacle may oppose the free access of external air, it is perfectly open below,

and stands upon an iron tripod. The grate is made of flat bars, set on edge, with considerable interstices between them. To the upper part A B is added a chimney, or tube of baked earth, eighteen feet long, and equal in width to nearly half the diameter of the furnace. Lavoisier recommends, as a thing of importance, to make the tube F G A B as bad a conductor of heat as possible; it must therefore be constructed neither of iron-plate, nor of copper, as is commonly the case.

Another kind of furnace is that necessary for assaying. In this furnace the metal must, at the same time, be exposed to the most violent heat; and, secured from the contact of the air, become incombustible by its passage through the coals: on this account it has been called the assaying or cupelling furnace. It is generally of a square form (fig. 14); and, like the other furnaces, has an ash-hole A A B B, a fire-hole B B C C, a laboratory C C D D, and a dome D D E E. The laboratory is destined for receiving the muffle, which is a kind of small oven (fig. 10) made of baked earth, and close at the bottom. It rests on bars which traverse the furnace; and being adjusted to the door of the laboratory, is luted in with clay. It is in this small oven the cupels are placed, and the muffle is surrounded with charcoal: that above it being conveyed through the door I of the dome; and that below it, through the door K of the fire-hole. The air which enters through the apertures of the ash-hole, after having served for the purpose of combustion, escapes through the upper aperture E E of the dome. In regard to the muffle, the air penetrates to it through the door G, and promotes the oxidation of the metal. This furnace, however, is attended with the following inconvenience: if the door G of the laboratory is shut, the oxidation, for want of air, takes place slowly; while, on the other hand, if it is open, the current of cool air causes the metal to become fixed, and retards the operation. To obviate this inconvenience, hot air should be conveyed to the muffle from without, by causing it to pass through an earthen tube, kept in a state of ignition by the furnace itself; and thus the interior part of the muffle would never become cold.

A very useful kind of furnace is that invented by Dr. Black. It consists (fig. 15) of a cylindrical or elliptical body of sheet iron, coated within with a mixture of loam and clay. The aperture X at top is closed occasisnally with an iron saucer full of sand, which forms a sand-bath: B is the door of the fire-place, and C is the ash-pit register, which slides so as to admit more or less air. D is an iron tube which goes into the chimney of the room, to carry off the smoke.

Blow-pipes are used for directing the flame of a candle or lamp against any bit of ore or other substance required to be examined. They ought to have a bulb upon the middle of their stem, to contain the moisture that is formed from the breath, as fig. 16.

The blow-pipe contrived by Dr. Black, of a conical form, represented in fig. 17, is the most convenient: *a* is the nozzle.

Of simple substances.—The object of chemistry, in subjecting to experiment the different bodies in nature, is that we may thereby be enabled to examine separately the substances which enter into their composition. This science has, during the last thirty years, made a very rapid progress. Formerly oil and salt, as well as water, were considered as elementary bodies: now it is ascertained that they are compound substances. Salts, as we shall hereafter see, are composed of an acid with some base, and their neutral state is the result of this union. Acids again are formed by the combination of an acidifying principle (oxygen) which is common to all, and a radical peculiar to each particular acid. See Acid. The radicals of the acids are not always simple substances: they are often compounded of hydrogen and carbon. The bases of the alkaline salts are often not more simple than those of the acids; as has been proved with respect to ammonia, which is composed of hydrogen and azote. See Ammonia.

It results from our knowledge of the gases (see Air,) that there are a certain number of substances which we may consider as simple bodies, whether they are so or not, because no means have yet been discovered by which they may be decomposed.

The substances of this kind are,

- Simple substances, which may be considered as the elements of bodies.
  - Light
  - Caloric
  - Oxygen
  - Azote or nitrogen
  - Hydrogen
- Simple non-metallic substances, oxidable and acidifiable.
  - Carbon
  - Sulphur
  - Phosphorus
  - Muriatic radical
  - Fluoric radical
  - Boracic radical
- Simple, earthy, salifiable substances.
  - Lime
  - Magnesia
  - Barytes
  - Alumina
  - Silica
  - Strontian
  - Zirconia
  - Glucina
  - Yttria
- Simple metallic substances oxidable.
  - Platina
  - Gold
  - Silver
  - Mercury
  - Copper
  - Iron
- Simple metallic substances oxidable, and some of them acidifiable.
  - Lead
  - Tin
  - Zinc
  - Antimony
  - Bismuth
  - Cobalt
  - Nickel
  - Manganese
  - Uranium
  - Titanium
  - Tellurium
  - Columbium
  - Tantalium
  - Chrome
  - Arsenic
  - Molybdena
  - Tungsten.

These simple substances may be combined with each other, and with other substances, in order to form compounds.

Of light. The physical properties of light will be considered under OPTICS. This substance seems to have considerable influence upon many chemical processes. The effect of light upon vegetation is well known. Many flowers follow the course of the sun; and plants that grow in houses, seem solicitous, as it were, to get at the light. Plants that grow in the shade, or in darkness, are pale, and without colour: and when this is the case, they are said to be etiolated or blanched. Gardeners avail themselves of this fact to render vegetables white and tender. The more plants are exposed to the light, the more colour they acquire. Yet the dead vegetable is deprived of colour by exposure to it.

Vegetables are not only indebted to light for their colour, their taste and odour are derived from the same source. From this cause it happens that hot climates are the native countries of perfumes, odoriferous fruits, and aromatic resins. The action of light on the organs of vegetables causes them to pour out streams of pure air from the surfaces of their leaves, while exposed to the sun: whereas, on the contrary, when in the shade, they emit air of a noxious quality. Even animals, in general, droop when deprived of light; and it appears to be of great importance to the health and happiness of human beings.

All metallic oxydes, but especially those of mercury, bismuth, lead, silver, and gold, become of a deeper colour by exposure to the sun; some of them become perfectly revived, others only partially. Many bodies, if exposed to light, either at high or low temperatures, combine with it, and emit it again under certain circumstances. These are called solar phosphori. Substances of this kind have been prepared by various chemists; the principal of which are, the phosphorus of Canton, Baldwin, Homberg, and the Bolognian phosphorus. These have the property of shining in the dark. Various animal and vegetable substances seem to possess this phosphorus. The glow-worm is a remarkable instance. Dead fish, rotten sea-weeds, and great numbers of insects, have this property in a great degree.

Instruments for measuring the degree or intensity of light are called photometers.

Of caloric. All the bodies in nature are immersed in caloric, which penetrates their parts throughout, and which fills up the intervals left between the particles. In some cases the caloric is fixed in these bodies, and in such a manner as even to contribute to their solidity; but it often separates their particles also, by exercising on them a repulsive force; and it is on its greater or less action or accumulation that the transition of bodies from the solid state to the liquid, and from the liquid to the aeriform, depends.

		The combination of caloric with
Oxygen	forms	Oxygen gas, or vital air
Azote or nitrogen	—	Azotic gas, or mephitic air
Oxygen and azote	—	Nitrous gas
Oxygen and carbon	—	Carbonic acid gas, and gas oxide of carbon
Oxygen and the muriatic radical	—	Muriatic acid gas
Oxygen and the muriatic radical, surcharged with oxygen	—	Oxymuriatic acid gas
Oxygen and sulphur	—	Sulphurous acid gas
Oxygen and the fluoric radical	—	Fluoric acid gas
Ammonia	—	Ammoniacal gas
Hydrogen	—	Hydrogen gas
Hydrogen and sulphur	—	Sulphurated hydrogen gas
Hydrogen and phosphorus	—	Phosphorized hydrogen gas
Hydrogen and carbon	—	Carbonated hydrogen gas
Water	—	Aqueous gas, and so of all other evaporable liquids.

Of oxygen. Oxygen is a substance diffused in great abundance throughout nature; it forms nearly a third in weight of our atmosphere. Animals absorb a great quantity of it by respiration; and it combines with other bodies to convert them into oxides and acids.

A certain number of conditions must be united, in order that a body may be oxygenated. The first is, that the constituent particles of this body must not exercise between themselves an attraction stronger than that which they exercise on oxygen. If they do not possess this superior force of attraction for oxygen, it may be communicated to them artificially, by exposing them to heat; that is to say, by introducing into them caloric, which separating them from each other, diminishes the force of their reciprocal attraction, and allows them to exercise a more powerful one on the oxygen: oxygenation will then take place. The degree of heat necessary to produce this phenomenon is not the same for all substances: some may be oxygenated at a temperature so low that we never find them but in an oxygenated state. Of this kind is the muriatic radical, which never presents itself to us simply, but always in an acid, which it has been hitherto impossible to decompose. To oxygenate the greater part of bodies, and almost all simple substances, in general, it will be sufficient to expose them to the action of the atmospheric air, and to raise them to the proper temperature. The temperature necessary to oxygenate lead, mercury, and tin, is not greater than that in which we live; but on the other hand, a pretty high degree of heat is necessary to oxygenate iron and copper in the dry way, and when the oxygen is not assisted by the action of humidity. Sometimes the oxygenation takes place with great rapidity, and in that case is accompanied with heat, light, and even flame: such is the combustion of phosphorus in the air, and in oxygen gas. That of sulphur is much less rapid. Such also is the combustion of iron in pure oxygen gas. Example: If a piece of iron wire bent in a

spiral shape, as A (fig. 20.) is hung in a receiver B filled with oxygen gas, and by means of a small piece of phosphorus, it is inflamed, the metal will burn with the greatest brilliancy. Tin, lead, and the greater part of the metals, oxidate slowly, and without the disengagement of the caloric being sensible.

There is still another method of oxygenating simple substances. Instead of exposing them to oxygen united with caloric, the oxygen may be presented to them in union with some metal for which it has little affinity. The red oxide of mercury is one of those best fitted for accomplishing this object, because the oxygen in that state adheres very little to the metal: it is disengaged from it at that degree of heat at which glass begins to become red. The black oxide of manganese, the red oxide of lead, the oxide of silver, and almost all the metallic oxides, can in a certain degree, produce the same effect.

Every metallic reduction or revivification, is an oxygenation of charcoal or some other combustible matter by a metallic oxide. The charcoal, by combining with the oxygen and caloric, escapes under the form of carbonic acid gas, and the metal remains pure and revived.

All combustible substances may be oxygenated also by combining them either with the nitrate of potash, or that of soda, or with the oxygenated muriate of potash. At a certain degree of heat the oxygen abandons the nitrate or muriate, and combines with the combustible body, but with great violence. The reason is as follows. The oxygen, in combining with the nitrates, and particularly with the oxygenated muriates, enters along with a quantity of caloric almost equal to that necessary for constituting it oxygen gas. At the moment of its combination with the combustible body, all this caloric becomes suddenly free, and produces terrible detonations. This method of oxygentions, therefore, must not be attempted but with the utmost caution, and when very small quantities of matter are employed.

There are different degrees of oxygenation: the first degree forms oxides, the second forms weak acids, the third strong acids, and the fourth hyperoxygenated acids.

The combination of oxygen with

Simple non-metallic substances.

- Caloric — forms oxygen gas
- Hydrogen — water

	Degrees of oxygenation
Azote	1, — base of atmospheric air 2, — nitrous oxide 3, — nitrous gas 4, — nitric acid
Carbon	1, — oxide of carbon 2, — carbonic acid
Sulphur	1, — oxide of sulphur, soft sulphur 2, — sulphurous acid 3, — sulphuric acid
Phosphorus	1, — oxide of phosphorus 2, — phosphorus acid 3, — phosphoric acid
The muriatic radical	1, — muriatic acid 2, — oxymuriatic acid 3, — hyperoxymuriatic acid
The fluoric radical	1, — fluoric acid
The boracic radical	1, — boracic acid.

The combination of oxygen with

Simple metallic substances.

	Degrees of oxygenation
Gold	1, forms yellow oxide of gold 2, — red oxide of gold, precipitate of Casius
Platina	1, — yellow oxide of platina
Silver	1, — oxide of silver
Copper	1, — reddish-brown oxide of copper 2, — green and blue oxide of copper
Iron	1, — black oxide of iron 2, — yellow and red oxide of iron
Tin	1, — grey oxide of tin 2, — white oxide of tin
Lead	1, — grey oxide of lead 2, — yellow and red oxide of lead
Mercury	1, — black oxide of mercury 2, — yellow and red oxide of mercury
Bismuth	1, — grey oxide of bismuth 2, — white oxide of bismuth
Cobalt	1, — grey oxide of cobalt
Nickel	1, — oxide of nickel
Zinc	1, — grey oxide of zinc 2, — white oxide of zinc
Antimony	1, — grey oxide of antimony 2, — white oxide of antimony
Arsenic	1, — grey oxide of arsenic 2, — white oxide of arsenic 3, — arsenic acid
Manganese	1, — black oxide of manganese 2, — white oxide of manganese
Tungsten	1, — oxide of tungsten 2, — tungstic acid
Molybdena	1, — oxide of molybdena 2, — molybdic acid
Titanium	1, — oxide of titanium
Chrome	1, — oxide of chrome 2, — chromic acid

In the mineral kingdom almost all the oxidable and acidifiable radicals seem to be simple substances; but in the vegetable kingdom there are scarcely any which are not composed of two substances, hydrogen and carbon. Azote and phosphorus are often joined with them, and the result is radicals with four bases.

From these observations, it appears that the oxides and the animal and vegetable acids may differ from each other three ways. 1st. By the number of acidifiable principles which constitute their base; 2d, By the difference in the proportions of these principles; 3d. By the different degrees of oxygenation. This is more than sufficient to account for the great number of varieties which nature exhibits to us. It thence appears, therefore, that some of the vegetable acids can be converted into each other. Nothing is necessary for this purpose but to change the proportion of carbon and hydrogen, and to oxygenate them more or less. Carbon and hydrogen, by the first degree of oxygenation, give tar-

tareous acid; by a second degree oxalic acid; and by a third the acetous, or acetic acid.

Of azote or *nitrogen.* Azote is a principle diffused in great abundance throughout nature: when combined with caloric, it forms azotic or mephitic gas, which in volume is three fourths of the atmosphere, and in weight, somewhat less than atmospheric air. It always remains in the state of gas at the temperature and pressure of the atmosphere which we experince; and we are unacquainted with any degree of compression or cold capable of reducing it to the solid, or even to the liquid state. Azote is one of the essential constituent parts of animal matter; it is combined in them with carbon and hydrogen, and sometimes with phosphorus; the whole being connected by a certain portion of oxygen, which reduces them to the state of oxide, or to the acid state, according to the degree of oxygenation.

The nature of animal matters, therefore, may vary, like that of vegetable matters, three ways: 1st, By the number of the substances which enter into the combination of their radicals; 2d, By the difference in the proportion of these substances; 3d, By the different degrees of oxygenation.

The combination of azote with

Simple substances.
- Caloric — forms azotic gas
- Oxygen — Degrees of oxygenation
  - 1, the base of atmospheric air
  - 2, nitrous oxide
  - 3, nitrous gas
  - 4, nitric acid
- Hydrogen — ammonia
- Carbon, Hydrogen, and sometimes Phosphorus, Oxygen — animal matters.

Of hydrogen. Hydrogen is one of the constituent principles of water, and thence it has received its name. It forms in the composition of water fifteen hundredth parts of its weight, while oxygen forms the other eighty-five parts. The affinity of hydrogen for caloric is so great, that it constantly remains in the state of gas at the degree of heat and pressure in which we live; it is impossible, therefore, to procure it free from all combination, and consequently we are unacquainted with the nature of this principle. It it one of the most abundant principles in nature; for besides entering into the composition of water, which is itself so abundant on the earth, it is one of those principles which act the most conspicuous part in the vegetable and animal kingdoms, by combination with different substances.

Having already referred to the production of hydrogen gas, (see AIR, p. 31) we shall now show the means of obtaining it by experiment.

Exp. Let the gun-barrel *x b* (fig. 21, Plate XXX) pass through a furnace F, and adjust to one extremity of it the bent tube A, and let the other extremity terminate in the tube B, carried under the receiver C. When the apparatus is thus disposed, and the several parts luted together, the gun-barrel must be brought to a red heat, and the water poured in drop by drop through A; and when it comes in contact with the gun-barrel, it is decomposed; the iron seizes on the oxygen of the water, and the hydrogen escapes through B in a state of gas.

This gas may also be obtained by pouring a solution of sulphuric acid over filings of iron or zinc.

Exp. Put iron filings into the jar A with two tubulures *a* and *b*, adjust to *b* the small glass tube ending in a capillary bore, and through *a* pour the diluted sulphuric acid: the gas will speedily be disengaged; and if a taper is applied to *x*, it will continue to burn with a fine blue flame as long as the decomposition goes on. This is called the philosophical candle.

The combination of hydrogen with

Simple substances.
- Caloric — forms hydrogen gas
- Oxygen — water
- Azote — ammonia, or volatile alkali
- Sulphur — the base of sulphurated hydrogen gas
- Phosphorus — the base of phosphorized hydrogen gas
- Carbon
  - the base of carbonated hydrogen gas
  - fixed and volatile oils
  - the radicals of the vegetable acids and when azote and phosphorus are joined with it
  - the radicals of the animal kingdom.

Of carbon. Carbon appears to be a simple substance, for hitherto it has not been possible to decompose it. Modern experiments seem to prove that it exists completely formed in vegetables, in which it is combined in hydrogen, and sometimes with azote and with phosphorus; and that it assists to form in them compound radicals, which are afterwards carried to the state of oxides or of acids, according to the proportion of oxygen united with them. To obtain the carbon contained in animal or vegetable matters, nothing is necessary but to expose them, first to a moderate and then to a very strong degree of heat, in order to decompose the last portions of water, which the charcoal strongly retains. In these operations chemists employ retorts of earthenware or porcelain, into which the combustible matters are introduced; and they are exposed to a strong heat in a reverberating furnace. The heat converts those substances which are susceptible of it into gas; and the carbon, which is more fixed, remains combined with a little earth and some fixed salts.

In the arts, the carbonization of wood is effected by a simpler and cheaper process. The wood is cut into pieces nearly of the same size and length; these pieces are disposed in heaps, and are covered with earth, in such a manner as to prevent all communication with the air, except what is necessary to make the wood burn, and to drive off the oil and water formed during the combustion; they are then kindled, and when they have burnt a sufficient time, the fire is extinguished by stopping the holes which served to introduce the air.

There are two methods of analysing charcoal, viz. 1st, By its combustion in oxygen gas: 2d, Its oxygenation by the nitric acid. In both cases it is converted into carbonic acid, and it leaves a residuum of lime, potash, and some neutral salts. It is not yet fully ascertained whether the potash exists in charcoal before its combustion.

Exp. Under a bell glass A, (fig. 23.) filled with oxygen gas, and inverted over mercury in the trough B C, introduce some charcoal in the saucer D. The charcoal must be wrapped in cotton; having also a small particle of phosphorus in it, in order that the whole may take fire upon the introduction of the heated wire H I through the mercury. The charcoal will then burn with great brilliancy. It will be found that to saturate 28 parts of carbon with oxygen, 72 parts of the latter are required, and the aeriform acid produced is equal in weight to the sum of the weight of the carbon and of the oxygen.

Exp. Very pure carbon may be thus procured: Put into a glass tube z (fig. 24.), closed at one of its extremities, and reduced to a capillary bore at the other, one part of phosphorus; and above it, at the distance of several inches, five parts of carbonate of lime, reduced to powder. Place the tube in the middle of the furnace F, so that the coals can heat the carbonate of lime only, the part of the tube containing the phosphorus being in the ash-hole. When the lime is brought to a red heat, the tube is to be raised, that the phosphorus may burn; the phosphorus lays hold of the oxygen of the carbonic acid, and becomes phosphoric acid; which unites to the lime, and forms phosphate of lime, while the carbon remains by itself.

The combination of carbon not oxygenated with

Oxygen	forms carbonic oxide and carbonic acid
Hydrogen	— the carbono-hydrous radical, fixed and volatile oils
Iron	— carburet of iron, or plumbago
Zinc	— carburet of zinc.

Of sulphur.—Sulphur is one of those combustible substances which have the greatest tendency to combination. At the common temperature of the atmosphere it is concrete; and it does not liquefy but at a heat several degrees higher than that of boiling water. It is found completely formed, and almost in its utmost degree of purity, in volcanic productions. It is found also, and much oftener, in the state of sulphuric acid, in argil, gypsum, &c.

To extract the sulphur of the sulphuric acid united to these substances, it must be deprived of its oxygen. This may be effected by combining it at a red heat with carbon: the carbon takes from it its oxygen, and thence is formed carbonic acid, which combining with caloric, disengages itself in the state of gas: the result then is a sulphuret, which may be decomposed by an acid: the acid unites to the base of the sulphuret, and the sulphur is precipitated.

Ex. We may here show the nature of sublimation: Put some lumps of sulphur into the vessel A (fig. 25.), to which the receiver B is adapted and luted round. A is put on a sand-bath, made hot by the furnace C; the sulphur melts, a smoke rises which is deposited in B in the form of vegetation, and hence it has been called flowers of sulphur. In this way sulphur may be combined with alcohol. Put powdered sulphur into a glass retort A (fig. 26.), suspend within it the bottle B containing alcohol, then put on the cover C, and adjust the beak x to the mouth z: lute the joinings, and heat the retort by the furnace F. The sulphur will be sublimed, and the alcohol will be volatilized. In this state the bodies meet, the sulphur unites to the alcohol, and a liquor will be obtained in z, called Boyle's liquor, which is sulphurated alcohol. We suppose that sulphur is held in combination by the alcohol, add to it some distilled water, and the sulphur will be precipitated.

The combination of sulphur not oxygenated with

	Degrees of oxygenation.	
Oxygen		1. forms oxide of sulphur, or soft sulphur 2. sulphurous acid 3. sulphuric acid
Hydrogen	—	the base of sulphurated hydrogen gas
Copper	—	sulphuret of copper, or pyrites of copper
Iron	—	sulphuret of iron, or pyrites of iron
Lead	—	sulphuret of lead, or galena
Mercury	—	sulphuret of mercury, or ethiops mineral; cinnabar
Zinc	—	sulphuret of zinc, or blende
Antimony	—	sulphuret of antimony, or crude antimony
Arsenic	—	sulphuret of arsenic, or orpiment; realgar
Potash	—	sulphuret of potash, or liver of sulphur with a base of fixed vegetable alkali
Soda	—	sulphuret of soda, or liver of sulphur with a base of fixed mineral alkali
Lime	—	sulphuret of lime, or liver of sulphur with a calcareous base
Magnesia	—	sulphuret of magnesia, or liver of sulphur with a base of magnesia
Barytes	—	sulphuret of barytes, or liver of sulphur with a base of ponderous earth
Ammonia	—	sulphuret of ammonia, or volatile liver of sulphur; fuming liquor of Boyle.

Of phosphorus.—Phosphorus is a simple combustible substance, for no experiment gives us reason to think that it can be decomposed. It was not known to the old chemists; and it was discovered in 1667 by a German, named Brandt, who made a mystery of his process. A short time after Brandt's secret was discovered by Kunckel, who published the process, and on that account it was called Kunckel's phosphorus.

It was from urine alone that this phosphorus was first extracted; and though the method was described, particularly by Homberg, in the Memoirs of the Academy of Sciences for 1722, the English, for a long time, supplied this article to all Europe. It was not made in France till 1737, when it was prepared for the first time in the Botanical Garden, in the presence of commissioners appointed by the Academy of Sciences.

At present it is extracted by a more convenient and economical process, from the bones of animals, which are real phosphate of lime. The simplest method, according to Gahn, Scheele, Rouelle, &c. is to calcine the bones of full grown animals until they are almost entirely white; to pound and sift them, and then to pour over them sulphuric acid diluted with water: but less than is necessary for dissolving the whole matter.

The sulphuric acid unites itself to the earth of the bones, and forms sulphate of lime: by these means the phosphoric acid is disengaged, and remains in a free state in the liquor. The liquor is then to be decanted, and

the residuum being washed, the water employed for this purpose must be added to the decanted liquor. The whole must then be evaporated, in order to separate the sulphate of lime which crystallizes in silky filaments, and you will thus obtain phosphoric acid, under the form of white transparent glass; which, when reduced to powder, and mixed with a third of its weight of charcoal, and distilled, will yield good phosphorus.

Phosphorus is found in almost every animal substance, and in some plants, which, according to chemical analysis, have an animal character. In this state it is generally combined with carbon, hydrogen, and azote, from which there result radicals with four bases. Phosphorus inflames at the temperature of 401 degrees.

It has so great an affinity for oxygen, as to decompose oxygen gas. Example. A receiver containing three or four quarts of oxygen gas (fig. 23) was placed over the mercurial trough B C, and about 61¼ grains of phosphorus distributed in the saucer D, and introduced under the receiver A, and kindled by means of a red-hot wire. The combustion took place with great rapidity, producing a brilliant flame, and the disengagement of a great degree of light and heat; the inside of the receiver became covered with white flakes, which were found to be concrete phosphoric acid. The quantity of oxygen gas employed was 16.2 cubic inches; after the absorption there remained 23 cubic inches, of course 139 inches of gas was absorbed. About 45 grains of phosphorus were burnt, and these combined with the oxygen formed the phosphoric acid. This experiment proves that, at a certain temperature oxygen has more affinity for phosphorus than it has for caloric; that the phosphorus decomposes the oxygen gas by seizing on its base; and that the caloric passes into the surrounding bodies, and produces in them heat.

The following experiment, made on a larger scale, proves the justness of the preceding results in a manner more rigorous and exact. Take a large glass balloon, A (fig. 27), the aperture of which, E F, is about three inches in diameter, and cover the aperture with a plate of ground glass, pierced with two holes to receive the two tubes, *y y y*, *x x x*, furnished with cocks. Before you cover it with the plate, introduce into it a supporter, C B, with a porcelain cup, D, containing 150¾ grains of phosphorus; and after you have closely shut the balloon, by luting on the glass plate, exhaust the balloon of air by connecting the tube *x x x* with an air-pump. Then weigh the whole apparatus by a nice balance, and fill the balloon with oxygen gas by means of the tube *y y y*, connected with a hydro-pneumatic machine. By the help of this machine you may ascertain in a very accurate manner, the quantity of oxygen gas introduced into the balloon, and that consumed during the course of the operation.

When every thing is thus arranged, kindle the phosphorus by means of a burning glass: the combustion will be exceedingly rapid, and accompanied with a large flame and a strong heat. In proportion as it is effected, there is formed such a quantity of white flakes, which attach themselves to the inside of the vessel, that it is soon rendered entirely opake.

When the whole apparatus has cooled, and you have ascertained the quantity of oxygen gas employed, weigh the balloon again before you open it. Then wash, dry, and weigh, the small quantity of phosphorus remaining in the cup, in order that it may be deducted from the whole quantity of phosphorus employed in the experiment. By observing these precepts, it will be easy to determine, 1st, the weight of the phosphorus burnt; 2d, the weight of the oxygen gas which has combined with the phosphorus; 3d, the weight of the flakes obtained by the combustion. This experiment will give nearly the same results as the preceding.

It thence appears that the phosphorus, in burning, combines itself with oxygen equal to one and a half of its own weight; and that the weight of the white flakes, or concrete phosphoric acid, produced, is equal to the sum of the weight of the phosphorus burnt, and that of the oxygen combined with it.

The combination of phosphorus not oxygenated with

	Degrees of oxygenation.	
Oxygen	1,	forms oxide of phosphorous
	2,	— phosphorous acid
	3,	— phosphoric acid
Hydrogen	—	phosphuret of hydrogen, or the base of phosphorized hydrogen gas
Azote	—	phosphuret of azote
Carbon	—	phosphuret of carbon
Sulphur	—	phosphuret of sulphur
Iron	—	phosphuret of iron, called formerly siderit

Of Earths.—By analysing earths, and freeing them from substances with which they are mixed, chemists have obtained nine simple or primitive earths, viz. lime, magnesia, barytes, alumina, silex, strontian, zirconia, yttria, and glucina.

Lime is rarely found in a pure state; it is contained in chalk, which may be deemed a neutral salt, being formed by the combination of lime with carbonic acid. The best process for obtaining lime in a state of purity is this: wash chalk in distilled water, brought to a state of ebullition, and then dissolve it in distilled acetous acid: this acid, by combining with the lime, expels the carbonic acid, which escapes under the gaseous form; then precipitate the lime by carbonate of ammonia, for the acetous acid abandons the lime, in order to combine with the ammonia, and the lime is precipitated: wash and calcine this precipitate, and the residuum will be pure lime.

Lime is soluble in water, but in very small quantities; more than 600 parts of water are necessary to dissolve one of it. It has a pungent, hot, and acrid taste; it turns blue vegetable colours green. It takes up water with avidity. When thrown into this liquid it splits, swells up, acquires a larger volume, and a great heat. It dissolves in acids without effervescence. The borate of soda and the phosphates of urine dissolve it also.

Lime, when alone, is infusible, even though the fire may be urged by oxygen gas, as has been proved by Lavoisier; but if combined with acids, it forms a fusible body, for lime is a salifiable base. Of all these base it is that most abundantly diffused throughout nature. See LIME.

Magnesia has never yet been found free from every kind of foreign matter. To procure it in the utmost degree of purity, crystals of the sulphate of magnesia (Ep-

som salt), of which it forms the base, must be dissolved in distilled water, and decomposed by alkaline carbonates: the sulphuric acid combines with the alkalies; the magnesia with the carbonic acid, and is precipitated. This precipitate must then be calcined, in order to disengage the carbonic acid; and what remains will be pure magnesia.

Pure magnesia is exceedingly white, tender, and in appearance spongy. When perfectly pure, it is not sensibly soluble in water. It excites no sensible savour on the tongue; and in this respect it is greatly different from lime. It gives a light green colour to the tincture of turnsole. Lavoisier has proved by experiment that magnesia is as infusible as lime. See MAGNESIA.

Barytes, or ponderous earth, has never yet been found pure and free from all combination. It is found under the pulverulent form, and exceedingly white. It gives a very slight tint of green to blue vegetable colours. Its specific gravity is from 4.2 to 4.3000. Analysis has proved that 100 parts of carbonate of barytes contain 62 of barytes, 22 parts of carbonic acid, and 16 parts of water. See BARYTES.

Alumina or pure argil is found chiefly in the different kinds of clay, of which it forms the base, and where it is often mixed with silex. To obtain it very pure, sulphate of alumina (alum) must be dissolved in water, and afterwards decomposed by alkaline carbonates. The alkali combines with the sulphuric acid, which then abandons the alumina; and the latter combines with the carbonic acid abandoned by the alkali. The alumina must then be freed from this acid by calcination; and after this process it will remain pure. It absorbs water with avidity, and becomes diluted in that liquid. It adheres strongly to the tongue. The borate of soda and the phosphates of urine dissolve it. When exposed to heat, it becomes dry, shrinks, and cracks. By the action of the fire it acquires so great hardness as to strike fire with steal: it is then no longer susceptible of being diluted in water. Alumina, even when perfectly pure, is completely fusible in the fire, if urged by a current of oxygen gas. The result of its fusion is a vitreous, opake, and very hard substance, which scratches glass in the same manner as precious stones do. See ALUM and ALUMINA.

Silex, or vitrifiable earth, is almost in its state of purity in rock-crystal: but to have it perfectly pure, one part of beautiful rock-crystal must be fused with four parts of pure alkali; the mixture must then be dissolved in water, and precipitated by an excess of acid; the precipitate will be pure silex, which is rough and harsh to the touch; its particles, when diluted in water, are easily precipitated.

The fluoric acid dissolves silex exceedingly well: it is also the solvent of glass. Alkalies dissolve silex in the dry way, and with it form glass. Silex cannot be fused by a burning lens; but by exposing it to a fire, urged by oxygen gas, Lavoisier produced a commencement of fusion on its surface. See SILEX.

Strontian was discovered by Dr. Hope, professor of chemistry at Glasgow. It is found in the state of a carbonate, that is, combined with carbonic acid, in a vein of lead ore, at Strontian in Argyleshire, in the western part of Scotland. It has been found also combined with carbonic acid at Lead-hills, in the same country. Some of it has since been discovered at Montmartre in France, combined with sulphuric acid; and it is found in quantities in the neighbourhood of Bristol.

Strontian was at first confounded with barytes: which indeed it resembles in several respects, though it differs from it in others.

Carbonate of strontian is decomposed by the sulphuric acid, and carbonic acid is disengaged: the sulphate of strontian, thus obtained, is very little soluble in water. It dissolves with effervescence in the nitric and muriatic acids, and carbonic acid is disengaged. These nitrates and muriates of strontian are not deliquescent, and are decomposed by the sulphates of lime, potash, and others. It may be deprived of its acid by calcination; its earth is then soluble in water, but in greater quantity in boiling than in cold water, for a part of it is precipitated by cooling.

The carbonate of strontian is lighter than carbonate of barytes: the specific gravity of the latter is from 42. to 43.000, that of the carbonate of strontian is only from 36. to 37.000. Analysis has proved, that 100 parts of the carbonate of strontian contain 62 parts of strontian, 30 parts of carbonic acid, and 8 parts of water. See STRONTIAN.

Zirconia is a simple earth, lately discovered by Klaproth, in the jargon of Ceylon, of which it is a constituent part, and even the most abundant; for it has been found by analysis, that 100 parts of the jargon of Ceylon contain 64 parts and a half of zirconia, 32 parts of silex, and two parts and a half of the oxide of iron. To obtain zirconia pure, it must be united to the muriatic acid, with which it forms a muriate of zirconia; this muriate must be dissolved in a large quantity of water, and the zirconia must be precipitated by potash: if it is carefully washed, and then brought to a red heat in a crucible, it will be perfectly pure. Calcined zirconia has a white colour. It is rough to the touch like silex; it has no taste, and is not soluble in water. Its specific gravity is at least 43.000; that of distilled water being 10.000.

When separated from its solutions by caustic alkalies, this earth retains a pretty large quantity of water, which gives it the semi-transparency of horn; it has then the appearance of gum-arabic, both by its slightly yellow colour and its fracture and transparency. It is susceptible of uniting with carbonic acid. It unites also with the sulphuric and nitrous acids: alkalies, and the first six primitive earths, separate it from the latter acid. It will not alone fuse by the blowpipe; but it fuses with the borate of soda, and gives a transparent colourless glass.

Yttria is also a newly discovered earth, and will be described under the article YTTRIA.

Glucina is a simple earth, lately discovered by Vauquelin, in the aigue-marine, called the occidental. It is a white granulated earth, which effervesces with acids. In 100 parts of this aigue-marine there are 14 of glucina. It is soluble in the carbonate of ammonia, as well as in the sulphuric acid. In the latter case, the solution has at first a saccharine, and afterwards an astringent taste. Its crystals are sweet, like the solution. It has some resemblance to alumina: as it is soft to the touch, adheres to the tongue, is light, dissolves in potash, and is precipitated from its solution by ammonia. But it differs from alumina by its combinations with acids being ex-

ceedingly sweet, by giving no alum when mixed with sulphate of potash, by being entirely soluble in carbonate of ammonia, and by not being precipitated from its solutions by oxalate of potash and tartrite of potash, as alumina is.

It has been found by analysis, that 100 parts of earth contain 68 of silex, 15 of alumina, 14 of glucina, 2 of lime, and one of the oxide of iron.

Of Acids.—According to the theory of Lavoisier, all acids consist of a certain base, united to oxygen, which is considered as the cause of acidity. See ACID. We are already acquainted with the bases of the sulphuric, nitric, phosphoric, and arsenic acids; we know that hydrogen, carbon, and oxygen, form the bases of the vegetable acids; and that the same substances, in combination with nitrogen, constitute the animal acids, such as prussic, &c. But we are totally unacquainted with the bases of the muriatic, boracic, and fluoric acids. Acids are either solid, liquid, or gaseous. They excite a peculiar sensation on the palate, called sour. They change most of the blue vegetable colours red. Most of them unite to water in all proportions; and some have so strong an attraction for it, as to be incapable of appearing in the solid form.

All the acids combine with the alkalies. These combinations have been termed neutral salts. See ACID and ALKALI. These salts are easily formed by art; and nature exhibits a great number, especially of those which are formed by acids of simple radicals. Neutral salts are distinguished by two names; one expressing the acid, and the other the alkaline base. The first of these names may have two variations of termination, corresponding to two different states of the acid in the salt. The termination ate, is employed when the acid is one of those which are completely saturated with oxygen, and whose names end in ic; thus the salts compounded with the nitric acid, are called nitrates. Words terminating in ite, serve to distinguish the presence of those weak acids which are not fully saturated with oxygen, and which, when alone, have names ending in ous; thus, nitrites are salts compounded with nitrous acid. For the crystallization of salts, see CRYSTALLIZATION.

All metallic substances combine with at least some of the acids. But the alkalies and earths enter into the composition of neutral salts without any uniting medium; whereas the metals do not combine with acids, unless they have been first more or less oxygenated: we may therefore say, that the metals themselves are not soluble in acids, but only the metallic oxyds. When a metallic substance is put into an acid, the first requisite, in order that it may dissolve, is, that it become oxydated in it. For this purpose, it must take up oxygen, either from the acid, or from the water with which the acid is diluted; the oxygen then must have more affinity for the metal than it has either for the hydrogen or for the base of the acid; and consequently a decomposition, either of the water or of the acids, must take place.

On these observations the explanation of the principal phenomena of metallic solutions depend. In metallic solutions, an effervescence, or disengagement of gas, often takes place. The gas disengaged by nitric acid, is nitrous gas; that disengaged by sulphuric acid, is sulphurous acid gas, if it be this acid that has furnished the oxygen; but it is hydrogen gas, if the oxygen has been furnished by the water. Nitric acid and water being composed of substances which, taken separately, exist only in the state of gases, as soon as they are deprived of their oxygen, the other principle assumes the gaseous form. It is this rapid passage from the liquid to the gaseous state, that constitutes effervescence. The case is the same with the sulphuric acid.

In general, the metals do not take from these acids all their oxygen; they do not reduce the one to azote, and the other to sulphur, but to nitrous gas and sulphurous acid. Metallic substances dissolve without effervescence, when they have been previously oxidated; for in that case, the metal no longer has a tendency to decompose either the acid or the water. There is therefore no disengagement of gas, and consequently no effervescence.

No metal dissolves with effervescence in oxygenated muriatic acid. In this case, the metal takes from the acid its excess of oxygen; and the result is a metallic oxyd, and simple muriatic acid. There is no effervescence, because there is no disengagement of gas.

Metals which have very little affinity for oxygen, and which have not the power to decompose either the acid or the water, are insoluble in acids, unless they have been first oxydated. For this reason, silver, mercury, and lead, are not soluble in muriatic acid, when exposed to it in their metallic state; but if previously oxydated, they are exceedingly soluble, and the solution takes place without effervescence.

The following is a table of the acids hitherto known:

	Mineral acids.
Sulphurous,	Oxygenated muriatic,
Sulphuric,	Hyper-oxygenated muriatic,
Nitrous,	Carbonic,
Nitric,	Fluoric,
Muriatic,	Boracic,
	Mellitic.
	Metallic acids.
Arsenious,	Molybdic,
Arsenic,	Chromic,
Tungstic,	Columbic.
	Vegetable acids.
Acetic,	Gallic,
Malic,	Citric,
Oxalic,	Tartaric,
Benzoic,	Succinic,
Camphoric,	Suberic.
	Animal acids.
Phosphorous,	Lactic,
Phosphoric,	Saccho-lactic,
Sebacic,	Prussic.
Laccic.	

Of sulphurous acid.—This is sulphur combined with oxygen, but not to saturation. It is the sulphurous acid gas when absorbed by water. The salts formed by the combination of this acid with different bases, are called sulphites; they are not employed for any useful purpose; they are converted into sulphates by heat.

Of sulphuric acid.—Sulphuric acid, formerly called spirit or oil of vitriol, is formed by the combination of sulphur, which is its base, and oxygen. It is obtained when the combustion of sulphur is carried on very slowly with access of atmospheric air; but it is produced with more facility by the addition of saltpetre, now called nitrate of

potash, which furnishes oxygen abundantly, and enables the combustion to go on more rapidly.

In operations of this kind, on a large scale, the mixture of sulphur and saltpetre is burnt in large chambers, the sides of which are cased with plates of lead, and water is placed on the floor, to collect the sulphuric vapours. The water is afterwards put into large retorts, and distilled by a moderate heat; water slightly acid passes over, and concentrated sulphuric acid remains in the retort. This acid suffers congelation by intense cold; it is unctuous to the touch, attracts moisture from the atmosphere with great avidity, and, when mixed with water, produces a heat above that of boiling water. It acts rapidly on all inflammable susbtances, rendering them black, the acid itself becoming brown, or even blackish. It combines with nitrous acid, and forms a compound which dissolves silver, but scarcely any other metal.

Sulphates are neutral salts, formed by the sulphuric acid with certain bases. Thus, sulphate of potash, formerly called vitriolated tartar, is produced by the combination of the sulphuric acid and potash.

Sulphate of soda, formerly called Glauber's salt, is formed by the combination of soda with the sulphuric acid. It is found frequently in mineral waters. See SULPHUR.

Nitrous acid.—Nitrous acid exists in the state of gas, in the form of a red vapour; it is nitrous gas combined with a limited quantity of oxygen: it is rapidly absorbed by water, and, when combined with it, is of a yellow or orange colour. It emits copious orange-coloured or red fumes. Different quantities of water convert its colour to a deep blue, green, yellow, &c. while the vapours still continue of their original yellowish-red colour.

Liquid nitrous acid, generally called spirit of nitre in the shops, is only nitric acid (to be afterwards described), holding in solution a quantity of nitrous gas. If this nitrous acid is heated, the nitrous gas is disengaged, which coming into the air, attracts oxygen, and becomes nitrous acid gas, appearing in the form of red fumes, and the liquid is converted into colourless nitric acid.

The following is the process made use of for procuring nitrous acid: Take a quantity of sulphate of iron (martial vitriol), deprived of its water of crystallization by heat, and mix with it an equal weight of dry nitrate of potash; put the mixture into a glass retort, to which a very spacious receiver has been luted, containing a little water, and begin to distil with a very slow fire. As soon as the red vapours cease to come over, let the fire be slackened; and when the vessels are cooled, the receiver must be cautiously withdrawn, and its contents quickly transferred through a glass funnel into a bottle furnished with a ground stopper. It may also be obtained by decomposing nitrate of potash, by means of sulphuric acid, with the assistance of heat.

The nitrites are very little known.

Of nitric acid.—The constituent principles of this acid are oxygen and nitrogen (or azote). It differs from the last-mentioned acid, only in not having any nitrous gas in a loosely combined state. Oxygen and nitrogen with caloric, form nitrous gas, which, with a greater quantity of oxygen, forms nitric acid.

Nitric acid is transparent, liquid, and colourless; when diluted with water, it is sold in the shops by the name of aqua-fortis. It possesses in an eminent degree all the properties of acids. It is capable of oxydating all the metals, except gold and plantina. It thickens and blackens oils, converting them to a coal, or inflaming them, according to the nature of the oil and the degree of concentration of the acid. It is procured by redistilling nitrous acid, or at least heating it till it is deprived of its fumes. The combinations of nitric acid with different bases, are called nitrates. These salts have the property of detonating with, or inflaming charcoal, and other easily inflammable bodies, at a red heat. It is upon this property that the composition of gunpowder is founded, which consists of five parts of nitrate of potash, one of charcoal, and one of sulphur.

Nitrate of potash, nitre, or saltpetre, is formed by the combination of the nitric acid with potash. It is produced spontaneously in various situations, sometimes efflorescing on the surface of the earth, and on the walls of old buildings. It may be artificially produced by the putrefaction of animal and vegetable substances; light earths, such as lime and marl, ashes, the refuse of soap-manufactures, &c. being stratified for this purpose with straw, dung, and putrifying animal and vegetable substances, and wetted with urine, blood, dunghill-water, and the mother-waters of saltpetre, turned, and exposed to a current of air. It is formed in these processes by the extrication of nitrogen, by the decomposition of the animal and vegetable substances, which combines with the oxygen of the atmosphere, forming nitric acid; and this, uniting with the alkali, which is separated at the same time from these substances, forms the nitrate of potash. See NITRE.

Nitrate of lime, formerly termed nitrous selenite, is found adhering to, and embodied in, calcareous stone, and dissolved in various mineral springs. It is formed near inhabited places, and is yielded by the lixiviation of old plaister, and by the mother-waters of saltpetre, as they are termed by the manufacturers. It may be frequently observed as an efflorescence upon old damp walls.

Of muriatic acid.—Muriatic acid, formerly termed marine acid, or acid of sea-salt, is supposed to consist of oxygen, in combination with a peculiar but hitherto unknown basis; for it has never yet been decomposed. It exists in the gaseous state, and forms muriatic acid gas, which has been considered already. This, absorbed by water, constitutes liquid muriatic acid. The muriatic acid is diffused in great abundance throughout the mineral kingdom, and is united chiefly with soda, lime, and magnesia; it is found with these three bases in sea-water, and in that of several lakes. In mines of rock-salt it is for the most part united with soda.

The muriatic acid does not adhere very strongly to the earths and alkalies. The sulphuric acid is capable of separating it from them; and it is by means of this acid that chemists obtain the muriatic.

Experiment. Put eight parts of purified muriate of soda, reduced to fine powder, into the retort A (fig. 28), and five parts of sulphuric acid diluted with a small quantity of water. Adapt to the retort the matrass C, to receive the portion of impure sulphuric and muriatic acid which passes over towards the end of the operation. D, E, and F, are a series of bottles in which water is put, the quantity of which is equal to the weight of the salt employed. These bottles are furnished with safety-tubes, G G. The

joinings must be well luted, and the heat gradually increased till nothing more can be disengaged. The muriatic acid will pass over in the state of gas, and unite itself in a large proportion with the water in the receiver. The water thus saturated is muriatic acid. It is a colourless fluid. It emits copious white fumes in contact with moist atmospheric air, which is muriatic acid gas, that escapes from it, and condenses again, by combining with the humidity of the air. Its combinations with earths, alkalies, and metals, form muriates.

Muriate of potash, the febrifuge salt of Sylvius, is formed by the combination of muriatic acid with potash. It is found in sea-water and old plaister. It has a strong bitter disagreeable taste.

Muriate of soda, marine salt, common salt, is formed by the combination of muriatic acid with soda. It is found native in mines, in many places, but particularly in Poland and Hungary. It is also obtained by extracting it from sea-water by evaporation, &c. It is always contaminated by a quantity of muriate of magnesia, muriate of lime, and sometimes by the sulphate of lime. It occasions clay to fuse readily, and is employed in glazing earthenware. It assists the fusion of glass also. It has a penetrating pleasant taste, decrepitates on hot coals, and by great heat is volatillized.

Muriate of ammonia, or sal ammoniac, is formed by the combination of the muriatic acid with ammonia, and is found native in many parts, particularly in the neighbourhood of volcanoes. It is obtained artificially by sublimation, from the soot formed by the combustion of the excrements of animals which feed on saline plants.

Muriate of lime is found in mineral waters, but particularly in the waters of the sea, to which it contributes to give their bitter taste. It speedily deliquesces. It fuses with a moderate heat, and by calcination becomes the phosphorus of Homberg.

Muriate of barytes is not known to exist native. The sulphuric and fluoric acid decompose it very readily; hence this salt is highly useful to detect the presence of these acids in any mixture.

Of oxygenated muriatic acid.—Oxygenated muriatic acid is muriatic acid with an excess of oxygen. By this, however, the acid properties of the muriatic acid are not increased, as is the case with other acids, but, on the contrary, diminished. In the state of gas, when absorbed by water, it forms liquid oxygenated muriatic acid, which, in a liquid form, is of a greenish-yellow colour. It has a bitter taste, and a very suffocating odour. Instead of reddening blue vegetable colours, it has the remarkable property of destroying them entirely. It thickens oils and animal fats, and renders them less disposed to combine with alkalies. It is readily obtained by the distillation of muriatic acid with substances containing much oxygen, such as the oxyds of metals, particularly the native oxyd of manganese.

When it is exposed to the light, oxygen gas is separated, and the acid is reduced to the state of ordinary muriatic acid. It removes the stain of common ink, though it does not affect printers' ink. It is therefore used for cleaning old books and prints. Half an ounce of minium being added to three ounces of muriatic acid, will render it fit for this purpose. The muriatic acid, taking oxygen from the minium, or red oxyd of lead, is converted into oxygenated muriatic acid.

Nitro-muriatic acid, called formerly aqua regia, is an acid analogous to oxygenated muriatic acid. It is produced by adding muriatic acid to nitric acid, in the proportion of one part of the former to two of the latter. During this combination an effervescence takes place, heat is set free, and oxygenated muriatic acid gas is evolved: the action may be assisted by the application of heat. The mixture becomes yellow. This acid has the property of dissolving gold and plantina, which cannot be acted upon by any other acid; for the muriatic acid attracts part of the oxygen of the nitric acid, being thus converted partly into nitrous acid and partly into nitrous gas, whilst the muriatic acid becomes converted by this addition of oxygen into oxygenated muriatic acid, or nitro-muriatic acid. The same combination may be produced by mixing together oxygenated muriatic acid and nitrous gas. Oxygenated muriatic acid may be combined with a great number of the salifiable bases; the salts which it forms detonate with carbon and with several metallic substances. These detonations are exceedingly dangerous, because the oxygen entering into the muriatic acid, with a large quantity of caloric, its expansion gives rise to violent explosions.

Oxygenated muriate of potash is made by introducing the oxygenated muriatic gas into a solution of potash; its crystals, as well as those of the common muriate, being formed on evaporation in the dark. It gives a faint taste, with a sensation of coldness in the mouth; the crystals have somewhat of a silvery appearance, and emit light by attrition. It is decomposed by the action of light, parting with its oxygen, and becoming simple muriate of potash. Heat also separates its oxygen from it, in the form of oxygen gas, 100 grains yielding 75 cubic inches of oxygen gas. When three parts of oxygenated muriate of potash, and one of sulphur, are triturated in a mortar, the mixture detonates violently. The same effect is produced when the mixture is struck with a hammer on an anvil.

Phosphorus detonates with oxygenated muriate of potash with a prodigious force. Similar effects are produced with other inflammable substances, or with metallic bodies. The oxygenated muriate of potash increases the blackness of ink; and the colours of log-wood, weld, cochineal, and archil, are improved by it, if no heat is employed. When employed in the composition of gunpowder, instead of nitre, the effects produced by its ignition are augmented in a very great degree, and the mixture will explode by mere trituration.

In this and other salts formed in the same way, the acid gets a still greater dose of oxygen, and is denominated hyper-oxymuriatic acid; but it cannot be separately exhibited.

Of carbonic acid.—This acid, already noticed under carbonic acid gas, exists in the gaseous state; and in combination with different bases it constitutes carbonates.

Carbonate of potash, formerly called mild vegetable alkali, is made by exposing a solution of alkali to the carbonic acid gas until saturated. It has now less of the urinous taste, but still changes the blue colour of violets to a green. It does not attract moisture from the air,

but rather parts with its water of crystallization. By exposure to heat it loses its acid, is rendered pure alkali, and is capable of uniting with silex, and forming glass. It is decomposed by quick-lime, and by all the acids.

Carbonate of soda was formerly termed mild mineral alkali. It is decomposed by quick-lime, by the acids, and by fire, in the same manner as the former carbonate.

Carbonate of ammonia, or concrete volatile alkali, may be obtained from many animal substances, but it is not found naturally. It is formed by the combination of carbonic acid with ammonia. When the muriate of ammonia is heated with carbonate of lime, the products are muriate of lime and carbonate of ammonia, which latter sublimes in a solid form.

Carbonate of lime, called also mild calcareous earth, chalk, &c. is formed by the combination of carbonic acid and lime. It has not been crystallized by art, although found variously crystallized in its native state. By intense heat the acid is disengaged, and pure lime remains. It is decomposed by almost all the acids, their superior degree of attraction for lime forming other calcareous salts, the carbonic acid escaping in a gaseous form, and occasioning effervescence.

Carbonate of barytes has no taste, is not altered in the air, is almost insoluble in water, but is decomposed by heat and by all the acids. It is poisonous.

Carbonate of magnesia, or the common magnesia of the shops, is obtained by precipitation from the sulphate of magnesia. It is soluble in water in the proportion of several grains to an ounce. It loses its water and acid by calcination, the residue being pure magnesia, sometimes called calcined magnesia. See CARBON.

Of fluoric acid.—The composition of this acid is unknown. In a gaseous state it forms fluoric acid gas; united to water, it constitutes liquid fluoric acid. It exists completely formed in fluate of lime, known under the name of fluor, or Derbyshire spar. It is combined in it with calcareous earth, forming an insoluble salt. To obtain this acid alone, and separated from its base, put fluor spar into a leaden retort, and pour over it sulphuric acid; adapt a leaden receiver to the retort, half-filled with water, and expose the retort to a gentle heat. The sulphuric acid seizes on the basis of the spar, and forms with it sulphate of lime; and the fluoric acid passes over in the state of gas, and is absorbed by the water in the receiver. If it is received in a mercurial apparatus, it will pass over in the state of gas.

The distinguishing property of the fluoric acid is its power of dissolving silex. Its odour resembles muriatic acid. When exposed to moist atmospheric air, it emits white fumes. Its action upon all inflammable substances is very feeble; it does not afford oxygen to them. It has no action upon most of the metals, but it dissolves many of their oxyds. It must be kept in well-closed leaden or tin bottles, or glass phials, coated within with wax or varnish. It is employed for etching on glass. See FLUOR.

Of boracic acid.—The boracic acid, before known under the name of Homberg's sedative salt, is a concrete acid extracted from borax, a salt brought from India. Its base is unknown. It exists in brilliant, glittering, white scales, soft, and unctuous to the touch. Its taste is bitterish, with a slight acidity. When mixed with burning spirit of wine, it causes a green, surrounded with a white flame. To extract boracic acid from borax, the latter must be dissolved in boiling water; the liquor is then to be filtred while very warm, and sulphuric acid poured into it: this acid seizes on the soda of the borax; and the boracic acid, being separated, becomes free. By cooling it my be obtained under a crystallized form.

Borate of soda, or borax, is formed by the combination of the boracic acid with soda. It is found in a crystallized state at the bottom of certain salt-lakes, in a barren volcanic district of the kingdom of Thibet. A still purer kind comes from China. It is obtained in a pure state by a second crystallization, being previously calcined to destroy the greasy matter. When purified, it is white and transparent. It has a cooling taste, and renders the blue vegetable infusions green. Exposed to a moderate heat, it melts with its water of crystallization; and is reduced into a white opaque light mass, when it is commonly called calcined borax. It serves as a flux to vitrifiable earths; it also vitrifies clay, but less completely. It is employed in forming reducing fluxes; and it may also be used in producing the fusion of glass. In soldering metals, it is highly useful, cleansing the surface of the metal, and assisting the fusion of the solder. See BORAX.

Of mellitic acid.—A yellow mineral somewhat resembling amber, found at Arten in Thuringen, has been found by Klaproth and Vauquelin to consist of alumina combined with a peculiar acid, which (from mellite the name of the mineral) is called the mellitic acid. It is crystallizable, soluble in water, decomposable by heat, and forms with the salifiable bases peculiar salts called mellats.

Of arsenious acid.—Formerly chemists were embarrassed with the nature of the poisonous substance known in commerce by the name of white arsenic. Experiments have shown that this substance is the metal arsenic, oxygenated in the first degree. It is therefore called arsenious acid. It possesses a weak acid taste; it sensibly reddens the tincture of litmus. If placed on burning coals, or on a red-hot iron, it is volatilized in the form of a white vapour, which has a strong smell resembling garlic. It is in a small degree soluble in water. The white arsenic of the shops is chiefly obtained from arsenical ores of cobalt. These are thrown into a furnace resembling a baker's oven, with a long flue, or chimney, into which the fumes pass, and are condensed into a greyish powder. This is refined by a second sublimation in close vessels, with a little alkali. As the heat is considerable, it melts the sublimed arsenic into opaque crystalline masses, which are known in commerce by the name of white arsenic.

Of arsenic acid.—Arsenic acid is produced only by art. It appears in the form of a white pulverulent matter. All the preparations of arsenic are deadly poison; the hydro-sulphurets are the best antidotes. A weak solution of hydro-sulphuret of potash, soda, or lime, is therefore often administered with success, if given in time, to persons who have been poisoned by arsenic. Sulphureous mineral waters may also be given. In such cases oil, milk, butter, &c. which are too often resorted to, should never be employed, if a sulphuret, or hydro-sulphuret, can possibly be procured.

Of tungstic acid.—This acid does not exist in an uncombined state in nature. It is procured from a mineral called tungsten, which is a combination of this acid with

lime (tungstate of lime), or from wolfram, which is this acid united to iron and manganese. It appears in a pulverulent form, harsh to the touch. It is tasteless, and insoluble in water. It is not capable of turning blue vegetable colours red, until it has been first rendered soluble by ammonia. It is of a yellow colour, which becomes blue on being exposed to the light.

Of molybdic acid.—We are indebted to Mr. Hatchett for a thorough knowledge of the properties of this acid, and of all its combinations. It is molybdena oxygenated; for this metal is susceptible of oxygenation to such a degree as to become a concrete acid. It is soluble in about 570 parts of water. The solution reddens tincture of litmus. It is not applied to any use.

Of chromic acid.—This acid is very little known. In nature it is found combined with oxyd of lead, in the mineral called chromate of lead, or the red-lead of Siberia; also united to iron, alumina, and silex, in the substance called chromate of iron.

Of columbic acid.—This acid is as little known as the last. It is found in the newly discovered ore called columbium, or columbat of iron.

Of acetous acid.—This acid exists, mixed with other substances, in common vinegar. Since this acid is very volatile, it is obtained pure by distilling vinegar in a sand-heat. It is also called distilled vinegar, and is perfectly colourless, and of a pleasant sour taste and odour. Its base is carbon and hydrogen; the addition of oxygen forms acetous acid. The same principles form the bases of the other vegetable acids, but in different proportions.

The acetites of potash and soda, are obtained by neutralizing the carbonates of these alkalis with acetous acid, and evaporating and crystallizing the solution. It was formerly supposed, that when deprived of part of its carbon, it formed another state of the acid, which was called acetic acid: but it has been shown by Gren, that there exists but one state of the acid, and what was called acetic acid differed only in the degree of concentration.

Of malic acid.—This acid is found in the juice of unripe apples and other fruits, and is procured by saturating the juice of apples with potash, and adding a solution of acetite of lead till it no longer occasions a precipitate; wash this precipitate, which is malate of lead; pour over it sulphuric acid until the liquid acquires an acid taste without any mixture of sweetness, and filtre the whole in order to separate the malic acid from the sulphate of lead which is formed.

Of oxalic acid.—Oxalic acid, formerly called the acid of sugar, is prepared from sugar by treating it with nitric acid. It has a stronger attraction for lime than any other acid. It is therefore employed to discover the presence of lime in any solution. It is always concrete. It forms with alkalis, earths, and metals, salts called oxalates.

Of citric acid.—Citric acid is found in the juice of lemons and oranges, unripe grapes, and other sour fruits. It crystallizes, and when concrete is not changed by the air. It dissolves in water, and has a very pleasant acid taste. It is used for a variety of purposes, and of late extensively in the art of calico-printing.

Of tartaric acid.—The tartar found adhering to casks in which wine has been fermented, is a salt composed of a peculiar acid combined with potash, but in such a manner, that the acid is in considerable excess. The salt is known under the name of acidulous tartrat of potash, and the acid which enters into its composition is the tartaric acid. This may be obtained by dissolving two pounds of crystals of tartar in water, and throwing in chalk by degrees, until the liquid is saturated. A precipitate forms, which is tartrite of lime. By adding nine ounces of sulphuric acid, and five ounces of water, to this tartrite, and digesting them together for twelve hours, the tartaric acid is set at liberty, and may be cleared from the sulphate of lime by means of cold water. The acidulous tartrat of potash, or cream of tartar, is formed from crude tartar, by solution, and subsequent filtration and evaporation. See TARTAR.

Of benzoic acid.—This acid is obtained by sublimation from the resin called benzoin, and exists in the balsam of Peru and that of Tolu, and some other substances of this kind. It is also found in urine, and many animal substances. See BENZOIN.

Of camphoric acid.—The camphoric acid is camphor oxygenated to acidity, by boiling it with nitric acid. This acid exists in the form of white crystals, which effloresce in the air. Its taste is acid and bitter. It reddens blue vegetables. See CAMPHOR.

Of gallic acid.—This acid is found in the gall-nuts, bark of trees, and in all those vegetables called astringents. Its taste is sour and astringent. It reddens vegetable blues. It crystallizes. It has a strong tendency to unite with metallic oxyds. It forms with the several metals precipitates of different colours. With gold, it forms a brown precipitate; with silver, grey; mercury, an orange; copper, a brown; lead, a white; and iron, a black precipitate. The base of ink is iron, thus precipitated; one pound of powdered nutgalls being infused for four hours, without boiling, in common water, with six ounces of gum-arabic, and six ounces of sulphate of iron, or green copperas, good black ink is produced. To obtain gallic acid, dissolve two ounces of common alum in water, and precipitate the solution by letting fall into it a solution of potash; wash the precipitate well, and transfer it into a decoction of gallnuts (obtained by infusing one ounce of gall-nuts in sixteen of water, and evaporating the liquor to one-half), agitate the mixture frequently during the course of 24 hours, and then filtre it. The fluid which passes through the filtre is gallic acid; which may be obtained in the form of needle-shaped crystals, by evaporating it slowly till a pellicle appears, and then letting it stand undisturbed.

Of succinic acid.—This acid is obtained by distillation from amber, and is therefore called also acid of amber. It is very soluble in hot water, and crystallizes by cooling. See AMBER.

Suberic acid.—This acid is obtained by the action of nitric acid on cork. It reddens vegetable blues, and has the peculiar property of turning the blue solution of indigo in sulphuric acid to green.

Phosphorous acid.—When phosphorus is burnt slowly, and does not become completely saturated with oxygen, it forms an acid, called phosphorous acid. It is liquid, transparent, and of considerable density. It has an unpleasant taste, and emits a disagreeable odour when rubbed, and especially when warmed. It is more volatile than phosphoric acid.

Of phosphoric acid.—Phosphorus saturated with oxygen, forms phosphoric acid, which is capable of existing in a dry state. It dissolves in water, and affords a transparent fluid void of odour. When exposed to heat, it is rendered viscous, and by degrees becomes consistent, and loses its transparency. When urged by a violent heat, it melts into a transparent glass, which again attracts moisture when exposed to the air, and becomes converted into liquid phosphoric acid. When melted in an earthen crucible, it acts upon the crucible, and fuses into a glass, which is not soluble in water, and exhibits no signs of acidity. It has a strong attraction for all the alkalis and earths. This acid is obtained from bones, which are chiefly phosphate of lime. It may also be obtained by the rapid combustion of phosphorus in oxygen. See PHOSPHORUS.

Sebacic acid, called the acid of fat, is obtained from the fat of animals. It is concrete, and soluble in water. It is sour, and without odour.

Laccic acid has been discovered by Dr. Pearson, in a substance called white lac, formed by certain insects of the coccus tribe. By exposing this substance to such a degree of heat as was just sufficient to liquefy it, a fluid was obtained, to which the doctor has given the name of laccic acid.

Lactic acid is found in the whey of milk. It is concrete, and liquefies in the air. It is sour, and oxydates the metals.

Saccho-lactic acid, was discovered by Scheele, who obtained it by treating sugar of milk with nitric acid. It is also obtained by treating gum-arabic with nitric acid.

Of prussic acid.—The prussic acid is formed by exposing the horns, hoofs, or dried blood of animals, with an equal quantity of fixed alkali, to a red heat. The alkali is found to be neutralised by the acid thus formed, and, on evaporation, will yield a salt in crystals, which is then called prussiate of potash or of soda, according to the alkali which has been employed. The prussiates of alkali precipitate all metals from their solutions; the alkali uniting with the acid which holds the metal in solution, whilst the prussic acid unites with the metallic oxyd, and communicates to it a peculiar colour. Thus gold is precipitated of a yellow colour, lead of a white, copper of a brownish-red, and iron of a dark blue, forming a prusiate of iron, or the substance called Prussian blue. From this substance the prussic acid may be again separated, by digestion with pure alkali, the prussiate of alkali being again formed, and the iron left in the state of a brown oxyd. This acid has a sour taste and suffocating smell, but, except its capacity of combining with alkalis and metals, it manifests no conspicuous acid properties. It does not redden the most delicate vegetable blues.

For the remainder of the compounds formed by the acids with the salifiable bases, see the Tables.

Of metals.—Among the most useful substances in nature, are the metals. Many of the mechanic arts depend upon them; and without a knowledge of them, perhaps mankind would never have attained their present degree of civilization. Their use is still unknown to many nations inhabiting the numerous islands of the South Sea. They are seldom met with in the earth in a native or pure state, but generally in combination with oxygen, sulphur, arsenic, and the acids. In their different states of combination, they are said to be mineralized, and they are then called ores.

The ores of metals are generally found in mountainous countries, chiefly in crevices of rocks, forming veins of ore; which are distinguished into level, inclined, direct, or oblique, according to the angle they make with the horizon. The part of the rock resting on the vein, is called the roof, and that on which the vein rests, the bed of the vein. The cavities made in the earth, in order to extract these ores, are called mines. The metallic matter of ores is generally incrusted, and intermingled with some earthy substance, different from the rock in which the vein is situated, which is termed its matrix. This, however, ought not to be confounded with the mineralizing substance with which the metal is combined, such as sulphur, &c.

The art of distinguishing ores from each other, and the method of describing them with accuracy and precision, are called Mineralogy.

The art of assaying or analysing them, in order to ascertain the component parts, forms a branch of chemistry, called the Docimastic art. See ASSAYING.

To procure the pure metal from the ore, it is first cleared as much as possible from the foreign or stony substances with which it is blended, and which are called the gangue, by first reducing the ore to powder, in which state it is called slich, and then by washing. It is then torrified, or roasted, to dissipate the sulphur and arsenic; and lastly fused by the addition of some flux containing the coaly principle, to disengage the oxygen with which the metal has been impregnated during the previous calcination or torrefaction.

Metals are distinguished from all other bodies by a peculiar brilliancy, which is termed metallic lustre, and by their weight, or specific gravity; the heaviest fossil, not metallic, being lighter than the lightest metal. They are also distinguished by their malleability, or their property of being extended under the hammer, and their ductility, or the property of being drawn into wire: though these two qualities are not possessed by all the metals. They are fusible by a sufficient degree of heat, and when suffered to cool gradually, they crystallize into regular figures. (See CRYSTALLIZATION.) If continued in fusion, they lose their brilliancy, and become an opaque powder, or metallic oxyd, acquiring weight, and absorbing a certain portion of oxygen during the transition. This process was formerly called calcination; it is now called oxydation. The pure metal itself was formerly known by the name of regulus; as the regulus of tin, of gold, &c.

That metals are calcined or oxydated in consequence of their absorbing oxygen, is proved by this process taking place only when oxygen is present, and by their giving it out in exactly the same quantity and proportion on their reduction to their metallic state. They undergo this process also from the action of humidity. The water is decomposed, its hydrogen being dissipated, whilst its oxygen unites with the metal. They are soluble in acids, and are precipitated from them by alkalis. Some of the acids are decomposed during their combination with metals; their oxygen combining with the metal, forming a metallic oxyd, which is then dissolved by the remainder of the acid, and forms a metallic salt.

When perfectly fused, they are for the most part miscible, or combinable with each other, or with unmetallic substances, as sulphur, phosphorus, and charcoal. If urged by a stronger heat, they are converted into a vitriform substance, or metallic glass. These metallic glasses, as well as the oxyds, possess other properties than their regali. They are of different colours: and the metallic oxyds tinge the earthy and saline glasses with which they vitrify, with various colours conformably to the difference of their own nature. They do this frequently, even when added in but small quantity. Such metallic oxyds as do not themselves yield a transparent glass, may deprive another of its transparency if fused with it. On the combination of other glasses with the metallic ones, and on the colouring of the first by means of the latter, depends the preparation of artificial gems and glass pastes, the pigments for enamel and porcelain-painting, the enamel itself, and the glazings for earthenware.

The operation by which metallic glasses and oxyds are restored to the regaline form, is called the reduction or reviving of metals.

In their reduction from the oxyds and glasses, the addition of a combustible substance is always necessary; charcoal, for instance, or such matters as contain carbon; as soap, pitch, resin, fat, and oil. In the smelting-works, the fuel itself is employed as a means of reduction, by fusing the metal interspersed among the coals. Some metals, as iron and platinum, grow soft before they fuse, and on this depends their very useful property of being welded.

Metals are the best conductors of electricity and galvanism.

Of platinum.—Platinum is found only in a metallic form in small grains. It was unknown in Europe before the year 1748. It is brought from South America. It is the heaviest, hardest, and most infusible, of all the metals. It is ductile, and may be hammered into plates, or drawn into wire. It may be welded together in a white heat, is unalterable in the air, and is on this account found a very valuable material for making specula, or reflecting mirrors for telescopes. No acid acts upon it, except the nitro-muriatic. It is of a white colour, between that of silver and tin.

The process which is generally used for obtaining malleable platinum, is as follows: Triturate common platina (which is generally in grains) with water, to wash off every contaminating matter that water can carry away. Mix the platinum with about one-fifth part white arsenic, and one fifteenth part potash, putting the whole into a proper crucible in the following manner: having well heated the crucible, put in one-third of the mixture; apply to this a strong heat, and add one-third more; after a renewed application of heat, throw in the last portion. After a thorough fusion of the whole, cool and break the mass. Fuse it a second time, and if necessary, even a third time, till it comes to be magnetic. Break it into small pieces, and melt those pieces in separate crucibles; and in portions of a pound and a half of the platinum to each crucible, with an equal quantity of arsenious acid, and half a pound of potash. After cooling the contents of the different crucibles in an horizontal position, in order to have them throughout of equal thickness, heat them under a muffle, to volatilize the arsenious acid; and keep them in this state without increase of heat, for the space of six hours. Heat them next in common oil, till the oil shall have evaporated to dryness. Then immerse them in nitric acid, boil them in water, heat them to redness in a crucible, and hammer them into a dense mass. They are now fit to be heated in a naked fire, and hammered into bars for use. Platinum is generally mixed with iron, and therefore it is magnetic. It forms alloys with most of the metals. That with copper is the most useful; it takes a fine polish, and does not tarnish. See PLATINUM.

Of gold.—Gold is always found in nature in a metallic state. It is generally met with in grains, called gold-dust, mixed with the sand of rivers; being carried away by them, from the rocks and mountains, where it is found in leaves or ramifications, adhering to quartz, and other stones. It is found chiefly in Africa and Hungary: and some has been discovered lately in the county of Wicklow, in Ireland, where the largest piece of native gold hitherto seen was found. Its weight was 22 ounces, and it was almost pure. Small quantities of gold have been found in a vast variety of substances. Indeed, in very minute quantities it is frequently met with: and from this circumstance, and from its being found after chemical processes where none was ever expected, many of the supposed formations of gold by the alchymists have taken their origin. It has been obtained from rotten manure, garden-mould, uncultivated earth, and from vegetables.

It is of a rich yellow colour; and is the heaviest of the metals, except platinum. It is not very hard when pure. It is the most ductile of all the metals. Gold-leaf transmits light of a lively green colour; but silver, copper, and all the rest of the metals which can be formed into leaves, are perfectly opaque, being much thicker. Gold melts at 32 degrees of Wedgewood's pyrometer, and is volatilized by an intense heat, such as that of a mirror or lens. It cannot be oxydated by any heat of a furnace, but may by electricity and galvanism.

Gold is not acted upon by any acid, except the oxygenated muriatic, or nitro-muriatic acids, which latter was called from this aqua regia, because gold was named by the alchymists the king of the metals. This solution of gold, called nitro-muriate of gold, yields by evaporation crystals of a beautiful yellow colour, which, when dissolved in water, tinge the skin indelibly of a deep purple. When precipitated from this solution by tin, it forms the purple precipitate of Cassus, so much used in enamelling. This consists of on oxyd of gold, mixed with an oxyd of tin. If, into a solution of gold, a piece of charcoal is put, and exposed to the sun's rays, the gold will be revived, and appear in a metallic state on the charcoal, forming a kind of gilding.

Gold may be taken from its solution by æther, which then retains it in solution, forming an æthereal solution of gold. If any substance is dipped in the nitro-muriate of gold, and then exposed to a stream of hydrogen gas, the gold will be reduced, and the substance covered with it. When ammonia is added to a solution of gold, a yellow precipitate is formed, called fulminating gold, because it has the property of exploding when exposed to heat.

Gold is precipitated from its solution in a metallic

state by green sulphate of iron. Gold easily alloys with mercury, which is therefore employed for the purpose of extracting it rom the substances with which it is mixed. The mercury, being more volatile, is driven off by heat, and the gold remains free. With silver it forms an alloy of considerable ductility. Copper heightens its colour, and renders it harder without much impairing its ductility. Tin and lead considerably impair its tenacity. With platinum it forms an alloy which is very ductile. With zinc it affords a brittle and hard mixture, susceptible of polish. It unites well with iron, and hardens it remarkably.

On account of its peculiar property of not tarnishing in the air, it is much used for defending other metals; and on account of its beautiful lustre, it is much employed in ornaments. See GOLD.

Of silver.—Silver is often found native, and also combined with lead, copper, mercury, cobalt, sulphur, arsenic, &c. When found in the metallic state, it appears in grains or leaves, adhering to various substances. It is found in the greatest quantities in Peru and Mexico; but there are silver-mines in many other countries. When pure it is of a very brilliant white. It is malleable, ductile, and laminable, in a great degree, though inferior to gold in these qualities. It may be beaten out into leaves, which are only $\frac{1}{160000}$ part of an inch in thickness. It melts at 28 degrees of Wedgewood's pyrometer, and is volatilized in very high temperatures. It does not tarnish in the air, except when sulphureous vapours are present. It forms alloys with most of the metals. With gold it forms a metal of a greenish colour, called green gold. Copper makes it much harder, without lessening its ductility. It forms an amalgam with mercury. The alloy of British coinage is fifteen parts of fine silver and one of copper. It unites to phosphorus and sulphur, forming phosphuret and sulphuret of silver.

Silver is acted upon by the sulphuric and nitric, but not by the muriatic acid. With the nitric acid it forms a colourless solution, which stains animal and vegetable substances with an indelible black colour: hence it is used as a permanent ink, and is employed for dying human hair black; though, for this purpose, it should be used with great caution, and much diluted, as it is extremely caustic or corrosive. It is also employed for marking linen. Nitric acid dissolves more than half its weight of silver, the solution depositing crystals. When these are fused by a gentle heat, they lose some of the acid, and being poured into moulds, form the substance called lunar caustic (nitrate of silver), used in surgery.

Nitrate of silver, prepared with common silver, is greenish, but this is on account of the copper usually mixed with the silver. Silver is precipitated from its solution in nitric acid, by muriatic acid, in the form of a white curd; which, when fused, forms a semi-transparent mass of the consistence of horn, called horn silver, but more properly muriate of silver. It soon blackens in the air, and is very little soluble in water. Since the muriatic acid has a strong affinity for the oxyd of silver, and since the muriate of silver is not very soluble in water, the nitrate of silver is employed as a re-agent, to discover the presence of muriatic acid in any liquid; for if it contains that acid, muriate of silver will fall down in a white cloud, on dropping nitrate of silver into it.

The nitric acid sold in the shops is usually adulterated with muriatic or sulphuric acid, or with both: hence the nitrate of silver is used to free the nitric from the two latter acids. For this purpose nitrate of silver is poured into it by degrees, until no more precipitate is produced: after which it is rendered clear by filtring. Nitric acid thus purified is called by artists precipitated aquafortis; but it still contains some silver, from which it cannot be freed, except by distillation.

When precipitated from nitrate of silver by ammonia, it forms fulminating silver; a very dangerous preparation, for it explodes by the mere contact of any body. More than a grain cannot be exploded at a time with any safety. When mercury is added to the nitric solution of silver, a precipitation of the silver is formed, resembling vegetation in appearance, called arbor Dianæ, or the tree of Diana. See ARGENTUM ARBORESCENS. If a few drops of the nitrate of silver are put upon a piece of glass, and a copper wire placed in it, a beautiful precipitation of the silver will take place, in the form of a plant. The affinity of silver for other metals, and its solution in acids, are the properties on which PLATING, SILVERING depend. See SILVER.

Of mercury.—Mercury, called also quicksilver, always appears in a liquid state, in the common temperature of the atmosphere; but in intense cold, as at 40 below zero, it becomes solid, and is then malleable, resembling silver. It is found in nature, sometimes in a pure state, but chiefly united to sulphur, when it forms cinnabar; and sometimes to silver. It is also united to the acids, and to oxygen. It is mostly found in Spain and South America. Like other fluids, it boils, and is converted into vapour. This process is employed to separate it from other substances. It is acted upon by most of the acids. It combines with sulphur and phosphorus; and forms alloys with most of the metals, which are then called amalgams. On this property depend some of the methods of gilding and of silvering mirrors. When acted upon by heat and air for a long time, it absorbs oxygen, and is converted into a real oxyde, called precipitate per se, or red oxyd of mercury. When the heat is increased, this oxyd gives out its oxygen, the mercury reassuming its metallic appearance. When agitated long in air, mercury is converted into a black oxyd.

The sulphuric acid acts on mercury, if assisted by heat; sulphureous acid gas is then disengaged, and a white oxyd is formed. Hot water being poured on this, it becomes a yellow oxyd, called turbith mineral, the water holding in solution sulphate of mercury. The nitric acid dissolves mercury, even without heat, nitrous gas being disengaged; one part of the acid oxydates the metal, whilst the other dissolves the oxyd.

The nitrate of mercury is corrosive. When dry, it detonates upon coals. By a moderate heat it yields oxygen, or nitrogen gas; the remaining oxyd becoming yellow, and at length a lively red, being the red precipitate of mercury; and if fresh nitric acid is distilled from it three or four times, it appears in small crystals, of a very superb red colour. The muriatic acid does not sensibly act on mercury, except by long digestion; when it oxydates a part, which oxyd it dissolves. It completely dissolves the mercurial oxyds; and when these have a small quantity of oxygen, and are nearly in a metallic state, the

muriate of mercury is formed. When, on the contrary, it is saturated with oxygen, the oxy-muriate of mercury, or corrosive sublimate of mercury, is formed.

To obtain the mild muriate of mercury, mercurius dulcis, or calomel, equal parts of quicksilver and of oxygenated muriate are completely blended by trituration, and exposed to sublimation. A beautiful artificial cinnabar may be prepared, by triturating mercury and flowers of sulphur with a solution of caustic vegetable alkali, keeping it at a proper temperature, and afterwards washing it repeatedly with boiling water. See MERCURY.

Of copper.—Copper is found native, but in very small quantities. It is generally met with in the state of an oxyd, or united to acids and sulphur. There are many copper-mines in Britain, Germany, &c. The largest copper-mine perhaps known, is that at the Paris mountain, in the isle of Anglesea.

Pure copper is of a red colour, very tenacious, ductile, and malleable. It melts at 27 degrees of Wedgewood's pyrometer, and burns with a green flame. When heated in contact with air, it is changed into a blackish red oxyd, which by a more violent heat is converted into a brown glass. The nitric acid dissolves copper with effervescence, and the solution has a blue colour. The acid first oxydates the metal; a large quantity of nitrous gas is then disengaged, and the copper afterwards dissolves. This is nitrate of copper. The sulphuric acid does not dissolve copper, unless when concentrated; and very fine blue crystals, known under the name of sulphate of copper, are the result. This is what is commonly called blue vitriol. The muriatic acid does not dissolve copper, but when concentrated, and in a state of ebullition; the solution is green, the taste of which is caustic, and exceedingly astringent. The acetous acid, in a sufficient degree of concentration, dissolves copper; but when not sufficiently concentrated, it only imperfectly oxydates it, forming verdigris; which, being dissolved in vinegar, forms crystallised acetite of copper, known under the name of distilled verdigris. Iron precipitates copper from its solution. For this purpose nothing is necessary but to immerse the iron in the solution; the acid seizes on the iron, and abandons the copper. The copper thus precipitated is called copper of cementation. This process is employed for obtaining the copper found in water near mines of copper.

Copper may be alloyed with most of the metals. As an alloy of silver it renders it more fusible: this mixture is employed as a solder for silver plate. Copper, when alloyed with tin, forms bronze, a metal used for making bells, cannon, statues, &c. When alloyed by cementation with the oxyd of zinc, called calamine, it forms brass. With arsenic it forms white tombac. The salts formed with copper have a poisonous quality. It is employed for making kitchen-utensils, but very improperly, for as these vessels are liable to be corroded by the salts and acids used in culinary preparations, they often become dangerous, and may thus make us swallow slow poison. Kitchen-utensils of tinned iron are far preferable, because iron possesses no quality injurious to health. See COPPER.

Of iron.—No metal is so universally diffused throughout nature as iron. It is found in animals, in vegetables, and in almost all bodies. It is the most useful of all metals, as well as the most plentiful, otherwise it probably would be also the dearest. It is seldom found native, but combined with a great variety of substances, and it is particularly distinguished by its magnetical properties. It is the hardest and most elastic of the metals. It is very ductile, and possesses the property of being welded. It is very difficult to fuse.

Exposed to the action of water, iron soon rusts or oxydates. It attracts the oxygen and carbonic acid, and is changed into a brown substance, which is a mixture of oxyd of iron and carbonate of iron. Iron-filings agitated in water become oxydated, and assume the form of a black powder called martial ethiops. When iron ore is fused in large furnaces, it is made to flow into a kind of mould formed in sand. This first product, which is exceedingly brittle, and not at all malleable, is called cast iron. In this state, by pouring it into different kinds of moulds, it is formed into stoves, pipes, cannon, and other articles.

Cast or crude iron contains carbon and oxygen. The presence of the former appears from its coating the utensils employed in its fusion with plumbago or black-lead, which contains nine-tenths of carbon, and one of iron. Crude iron is in three states, white, grey, or black, according as it contains a larger proportion of carbon, an exact proportion of carbon and oxygen, or a larger proportion of oxygen. To render the iron malleable, it must be freed from the carbon and oxygen which it contains. For this purpose it is fused; and kept in that state for some time, stirring and kneading it all the while; by this the carbon and oxygen unite, and are expelled in the form of carbonic acid gas. It is then subjected to the action of large hammers, or to the pressure of rollers, by which the remaining oxyd of iron and other impurities are forced out. The iron is now no longer crystallized or granular in its texture; it is fibrous, and ductile, and is in a purer state, though far from being absolutely pure. It is capable of being welded and worked by hammers into any form. It is now called forged or wrought iron.

There are several varieties of iron in this state, arising from the intermixture of other substances. There is one kind of forged iron, which when cold is ductile, but when heated is extremely brittle. It is also fusible. This is termed hot-short-iron. Cold short-iron possesses precisely the opposite properties, being highly ductile while hot, but when cold extremely brittle. The causes of these peculiarities have not been perfectly explained. Iron is capable of being reduced to a third state, which is that of steel. It is converted into steel by exposing it to heat in contact with carbonaceous substances, which unite themselves with it. Thus we have three states in which iron may exist, viz. cast iron, forged iron, and steel.

Cast iron contains too great a quantity of carbonaceous substance: it may be called steel too much steelified; it is therefore exceedingly brittle, and not at all malleable.

Forged iron is iron purified from all foreign substances.

Steel is formed by bedding in charcoal, in a close furnace, alternate layers of malleable iron and charcoal, and exposing them to a strong fire for six or eight days. This process is called cementation. During this operation, the iron combines with a quantity of carbon, and is converted into blistered steel. This is either rendered

more perfect and malleable by subjecting it to the operation of the hammer; or is fused, and cast into small bars, forming cast steel. Those kinds of cast iron which contain but little oxygen, may be converted into a sort of steel by a similar process. In this process, the iron gains an increase of weight by the carbon it has acquired.

Steel holds a middle rank between cast and forged, or malleable iron. It is composed of very small grains, and when hot, possesses a considerable degree of malleability. It is specifically heavier than forged iron. It is denser than forged iron, but it is not harder. To communicate to it the necessary hardness, it must be tempered; that is, after being exposed to a greater or less degree of heat, according to the required degree of hardness, it must be suddenly cooled by immersion in cold water. Tempering renders it harder, more elastic, and more brittle. It may be made so hard as to scratch glass. Steel, thus hardened, may have its softness and ductility restored by again heating, and suffering it to cool slowly. A polished bit of steel, when heated with access of air, acquires very beautiful colours. It first becomes a pale yellow, then of a deeper yellow, next reddish, then deep blue, and at last bright blue. At this period it becomes red-hot, and the colours disappear; at the same time that the metallic scales, or the black imperfect oxyd of iron which is formed, incrust its surface. All these different shades of colour indicate the different tempers the steel has acquired by the increase of heat. Artists have availed themselves of this property, to give to surgical and other sharp instruments those degrees of temper, which their various uses require. Tempered steel is more elastic, and harder, than iron.

Wootz, a metal brought from the East Indies, was examined by Dr. Pearson, who discovered that it was iron united to carbon, and also to oxygen. Iron combines with sulphur and phosphorus, forming sulphuret and phosphuret of iron. It combines also with most of the metals; but it was supposed till lately, that it could not be amalgamated with mercury. Mr. Arthur Aikin has, however, contrived a method of effecting this. Where iron is united to oxygen in the proportion of 73 parts of iron to 27 of oxygen, it forms the black or green oxyd of iron, which may be obtained by bringing a bar of iron to a red heat, and subjecting it to the hammer; the scales which fly off, are the black oxyd of iron. This oxyd is attracted by the magnet, and if exposed to a white heat in a crucible, will absorb 21 parts more of oxygen; and is then converted into the red or brown oxyde of iron, and will not be affected by the magnet.

Iron does not combine with oxygen, in more than these two proportions. Iron is acted upon by all the acids. The nitric acid is rapidly decomposed by iron. A portion of the oxygen of the acid oxydates the iron, which then dissolves, and the remainder of the acid passes off in nitrous gas. Sulphuric acid diluted with water being poured on iron, a considerable effervescence takes place, in consequence of the disengagement of the hydrogen gas of the water; its oxygen effecting the oxydation of the metal, while the acid dissolves the metal without being decomposed. This solution yields by evaporation the sulphate of iron. Common copperas is this salt in an impure state. See Iron.

Of lead.—This metal is scarcely ever found in the native state. It is chiefly mineralized by sulphur, and is then called galena. The pure metal is of a greenish colour. When cut it is bright, but soon tarnishes in the air. It may be easily cut with a knife, and it soils the fingers when rubbed. It has little or no elasticity. It fuses at 540 degrees Fahrenheit. When exposed to heat with access of air it fuses, and is oxydated at the surface. If this oxyd is removed, more is formed, and thus the whole may be converted into grey oxyd of lead, which when exposed to a strong heat, is converted into a yellow oxyd, called massicot. If this yellow oxyd is exposed to a still more violent heat, it assumes a beautiful red colour, and becomes red lead, or minium. Litharge is a semi-vitrified oxyd of lead, obtained by keeping a stream of air upon fused lead: it is generally procured in the process of separating silver from lead. If litharge is exposed to a strong heat, it becomes converted into glass of lead, which forms the basis of the common glazing for earthenware. Lead combines with sulphur and phosphorus. Nitric acid converts lead into a white oxyd. Sulphuric acid in a state of ebullition oxydates, by means of a portion of its oxygen, a considerable part of the lead exposed to its action; another part of the lead is dissolved and forms sulphate of lead. Muriatic acid poured over lead, and assisted by heat, oxydates one part of it, and dissolves another. The affinity of muriatic acid for the oxyds of lead is so great, that the latter decompose all the combinations of this acid. They decompose the muriate of soda, the muriate of ammonia, &c. and form muriate of lead, or patent yellow. The acetous acid corrodes lead, and the result is a white oxyd, known under the name of white lead. All the oxydes of lead are soluble in vinegar, and form acetat of lead, known under the name of sugar of lead.

Lead is applied to a great variety of uses in the arts. It is employed for making water pipes, for lining boxes, for covering houses, for musket bullets, for small shot, and various other purposes. It is sometimes mixed with the metal employed for tinning utensils of copper: this practice is highly dangerous, and deserves the severest reprehension and punishment. Lead forms alloys with other metals, which are used as solders.

Of Tin.—Tin is scarcely ever found native. It is generally combined with sulphur, iron, and other substances. It is of a colour approaching to that of silver, but somewhat duller. Next to lead, it is the softest, and the least elastic of all the metals. In tenacity it is superior only to lead; though not very ductile, it may be reduced to very thin leaves. It is less sonorous than copper, silver, or iron. Except cast iron, it is the lightest of all metals. It fuses with less heat than any of the other metals, and is a long time before it becomes red. It may be easily bent, and in that case emits a kind of crackling noise; it is the only metal which possesses this property.

When tin has been kept some time in a state of fusion, and is then exposed to the action of the air, its surface becomes wrinkled, and covered with a grey pellicle, which is oxyd of tin. If this first stratum is removed, the tin appears below in all its brilliancy; but it soon loses its splendour, and its surface is again oxydated. By continuing to expose it to heat, you may at

length oxydate the whole of it. This oxyd is what is called putty of tin, used for polishing mirrors, lenses, &c. and for rendering glass white and opaque, converting it into enamel.

Tin is soluble in sulphuric acid. With muriatic acid it forms muriate of tin, of great use in dyeing. Tin when fused detonates with nitrate of potash, and also with oxygenated muriate of potash when struck with a hammer. Tin combined with sulphur forms aurum musivum, used by the japanners. It alloys with other metals, forming solder. With lead and antimony it constitutes pewter, used for various domestic vessels. With mercury it is employed for silvering mirrors. See TIN.

Of Zinc.—This metal is mostly procured from calamine, which is a sort of oxyd of zinc. When it is mineralized by sulphur it is called blende. It is nearly of the colour of tin. It is scarcely at all ductile. Zinc, when exposed to heat, soon enters into fusion, and long before it becomes red; the degree of heat which is required for this purpose, being only a very little higher than that necessary to fuse lead: when brought to a red heat it burns with a blue flame, and throws out white flakes, called flowers of zinc.

The nitric acid, even when diluted with water, dissolves zinc with violence, and forms a nitrate of zinc. The sulphuric acid diluted with water dissolves zinc rapidly; in this the water is decomposed, and a great deal of hydrogen gas escapes. By evaporation may be obtained sulphate of zinc, or white vitriol in crystals. The muriatic acid dissolves zinc with effervescence; and hydrogen gas is produced in the same manner as with the sulphuric acid; afterwards there is a precipitation of black flakes, which is muriate of zinc. One part of zinc alloyed with three parts of copper, forms the metal called brass. See ZINC.

Antimony.—Antimony is rarely found native. It is generally combined with sulphur, forming sulphuret of antimony. It is of a whitish colour, and so brittle that it readily breaks under the hammer. Its interior texture appears to be laminated. It volatilizes entirely in the fire, and communicates the same property to metals with which it is mixed. It fuses at a degree of heat somewhat higher than that necessary to fuse zinc. If kept in fusion it oxydates, and is converted into grey oxyd of antimony. If the heat is increased, this is converted into white oxyd of antimony, known under the name of flowers of antimony. This oxyd is vitrifiable, and then becomes glass of antimony.

Antimony combines with phosphorus and sulphur. Wine and the acetous acid dissolve antimony, and then become emetic, the acid of tartar forms with it the well-known salt, the antimoniated tartrat of potash, or emetic tartar.

Antimony is employed in commerce in two states; 1st, under the form of crude antimony, which is nothing else than sulphuret of antimony freed from its matrix; 2nd, under the form of regulus of antimony, or metallic antimony. See ANTIMONY.

Of Bismuth.—Bismuth is often found native. It is also combined with oxygen, sulphur, iron, and arsenic. See BISMUTH.

Of Cobalt.—Cobalt has never been found but in a state of combination. It is found united to sulphur, arsenic, and other metallic substances. It is of a pale or grey colour, inclining to red; it is hard, but fusible. In the fire it has a considerable degree of fixity, and does not inflame, or emit fumes. It fuses, but requires almost as strong a degree of heat as is necessary to fuse iron.

Oxyd of cobalt, when freed from arsenic, is known under the name of zaffer. Zaffer, when fused with three parts of quartz, and one part of potash, forms glass of a beautiful blue colour. This glass pulverized forms smalt, from which the blue employed for colouring starch is made. It is used also by the painters of earthenware, porcelain, &c. and by enamellers. Cobalt is soluble in acids. The nitric and sulphuric acids dissolve it with effervescence. The muriatic acid does not dissolve cobalt cold; but by the aid of heat it dissolves a portion of it. The acid has a more powerful action on the zaffer, and the solution is of a beautiful green colour. The nitro-muriatic acid dissolves cobalt, and forms a sympathetic ink. See COBALT.

Of Nickel.—Nickel is generally found in a metallic state. It was discovered not long since by Cronstedt, a Swedish mineralogist. It is of a reddish colour, very little malleable, and very difficult of fusion. When exposed to the air it oxydates, and very rapidly when heated. It forms alloys with most of the metals, and is acted on by most of the acids. See NICKEL.

Of Manganese.—This metal is found only in combination. It is generally united to oxygen, for which it has a strong affinity, so that it is very difficult to preserve it in a metallic state. The black oxyd of manganese is found very generally. It is procured in the greatest purity in the neighbourhood of Exeter, and is very much used for obtaining the oxygenated muriatic acid gas employed in bleaching. It is also used by glass makers for destroying the green or yellow tint of glass; and for this reason has been called glass maker's soap. It is also employed for giving a violet colour to glass and porcelain. In a metallic state it is of a grey colour, not at all malleable, and more infusible than iron. It alloys with all the metals, except mercury. See MANGANESE.

Uranium was discovered by Klaproth in 1789, in the mineral called pechblende, which is an oxyd of uranium. It is of a grey colour, very porous and soft; more difficult of fusion than manganese. It is very little known on account of its scarcity.

Titanium is a newly discovered metal. It was first observed in a mineral called menachanite, found in Cornwall, and afterwards in an ore called titanite. It is of a reddish yellow colour, and very infusible. It is very little known. See TITANIUM.

Chrome is a metal lately discovered by Vauquelin; respecting the nature and properties of which we are as yet little acquainted. Vauquelin gave it the name of chrome, because it communicates the red colour to the ruby, and the green to the emerald. It was found by this chemist in the state of an acid, in a substance before known under the name of the red lead of Siberia. The mineralizing substance of this red lead is a real acid, the radical of which is chrome. It is likewise found in France, combined with iron.

Arsenic is often found native. When combined with sulphur it is called orpiment. It is also often united with metals. See ARSENIC.

Molybdena is found united to sulphur. It is in this state very like plumbago. It is extremely difficult to obtain in a metallic state, and is therefore very scarce, and little known. It is capable of oxygenation, so as to form an acid. See MOLYBDENA.

Tungsten is never found pure, and is very scarce. It is acidifiable; and its combination with lime forms tungstate of lime. It is also united to iron and manganese, in the ore called wolfram. The metal is brittle, hard, and very infusible. It is very little known; but is said to have one valuable property, viz: that of rendering all vegetable colours fixed; but this does not appear to be certain.

For the remaining compounds into which metals enter, and the order of their affinities, &c. see SALTS and METALS.

Vegetable Substances.—Besides the substances which we have already described, nature exhibits another class which are called living, or organized beings. These are animals and vegetables, which at first sight appear to be very different from each other, yet it is not easy to say precisely, in what the difference between them consists.

Vegetables in general differ from animals, in the former being fixed to the earth, and not being able to change their situation; while the latter are possessed of locomotive power, which they are obliged to exercise, in order to procure food for their sustenance.

Almost all vegetables are composed of three principal parts: the bark, or exterior covering; the wood or woody fibre, which in trees constitutes the principal part; and the pith, which seems to correspond to the marrow of animals. The constituent principles of vegetables, are hydrogen, carbon, and oxygen. Those are common to all vegetables. Such other substances as exist in particular vegetables, are only essential to the composition of those in which they are found, and do not belong to vegetables in general. Of these elements, hydrogen and oxygen have a strong tendency to unite with caloric, and be converted into gas, while carbon is a fixed element, having little affinity with caloric. On the other hand, oxygen, which in the usual temperature, tends almost equally to unite with hydrogen or with carbon, has a much stronger affinity with carbon, when at the red heat, and unites with it, to form carbonic acid.

Vegetables are analyzed by various means, by heat, by acids, by water, and by fermentation. Some of these processes form products which did not exist in the living vegetables. Though all vegetables consist of hydrogen, carbon, and oxygen, yet these elements do not exist in them in a simple and uncombined state, but joined together in various proportions, forming a variety of compound substances, which, mixed together in an organic form, make up the whole vegetable. We shall now describe the principal substances which are to be met with in vegetables.

1. Mucilage. Various parts of vegetables impart to water, if boiled with them, a certain viscous consistency: this is called mucilage. Some trees suffer their mucilage to transude, either spontaneously or by incisions made in them. When it has become concrete by drying in the air, it is called gum. This substance is without taste; soluble in water, but not in oils or alcohol. It is not changed by exposure to the air. It appears to consist of oxygen, hydrogen, nitrogen, carbon and lime.

2. Oils. Oil was formerly supposed to be a simple substance; but Lavoisier proved that it is composed of carbon and hydrogen; it also contains a small portion of oxygen. Oils are divided into fat or fixed oils, and volatile and essential oils. Fixed oil is usually obtained by expression, chiefly from the seeds and kernals of plants. It is generally mixed with mucilage. It does not combine with water or alcohol. It has a great affinity for oxygen, which thickens it, and makes it pass into the concrete state. Some fixed oils, as linseed and walnut oil, dry of themselves, or become solid, in the air: but this property is much increased by boiling, and adding oxyd of lead, which constitutes drying oil. Fixed oils are volatilized by a strong heat, and when volatilized, take fire by the contact of an ignited body. When added to acids, they attract oxygen from the acids, and form a kind of resinous substance. With alkalis, they form soap; and dissolve sulphur and phosphorus.

Volatile oils are generally procured by distilling aromatic plants with water. The water rises, accompanied by the oil, part of which is dissolved in the water; but the greatest quantity separates to the surface, or the bottom. They are soluble in alcohol, dissolve resin, sulphur, and phosphorus, and are very inflammable. They attract oxygen; and by long keeping are converted into resin, charcoal, and water. See OIL.

3. Resins exist in the vessels of certain trees, and frequently exude from them spontaneously. Sometimes they are procured by making incisions in the trees, and sometimes by distilling the wood. They are considered as volatile oils combined with oxygen. They are soluble in alcohol and oils, but not in water. It is this property that renders them so valuable as varnishes. They are inflammable, and melt with a slight heat. The principal resins are the turpentines, mastic, copal, sandarac, &c. See RESINS, &c.

4. Gum resins appear to be a natural mixture of resin and mucilage. They are partly soluble in water, and partly in alcohol. Gum ammoniac, assafœtida, &c. are gum resins. See GUM.

5. Caoutchouc, or elastic gum, very much resembles a resin. It is very elastic, inflammable, and insoluble in water or fat. It is partly soluble in volatile oils, and entirely so in melted spermaceti, and in nitric ether. It gives out heat as often as it returns to its dimensions after strong tension. See CAOUTCHOUC.

6. Camphor is a volatile oil, rendered concrete by carbon. It is very inflammable, and sublimes by a gentle heat. It is soluble in ether, alcohol, acids, and oils. It is highly odorous, and has been supposed to prevent the spreading of contagious disorders; but this has been denied by some. See CAMPHOR.

7. Wax is a vegetable substance, found in the greatest quantity on the anthers of flowers. The surfaces of many leaves are also coated with it. It is collected by the bees. It is insoluble in water and alcohol, but soluble in volatile and fixed oils. It is very inflammable. Its principles are the same as those of volatile oil. See WAX.

8. Honey is chiefly formed in the pistils or female organs of flowers, whence it is collected by the bees. It appears to be sugar dissolved in mucilage. See HONEY.

9. Sugar is very extensively distributed through the vegetable kingdom. It is procured in the greatest quan-

tity from the sugar cane; but it may also be obtained from the sugar-maple, the beet-root, carrots, &c. Its constituent principles are oxygen, carbon, and hydrogen. See SUGAR.

10. Gluten is an elastic substance, very much resembling an animal matter, found in many vegetables, but chiefly in wheat flour. It is insoluble in water, and very slightly so in alcohol. It hardens by heat into a brownish transparent horny matter; and differs from all other vegetable substances by its containing a larger quantity of nitrogen and some ammonia.

11. Fecula, or starch, forms the principal part of the substance which is washed away in order to obtain the gluten from the grain. When the fluid is suffered to stand, a white powder subsides, which is the starch. It is not soluble in cold water nor in alcohol; but is soluble in hot water, forming with it a well known paste. Barley consists almost entirely of it. It appears to be only a slight alteration from mucilage, differing from that only by its being insoluble in cold water. There are also coloured feculæ, as indigo.

12. Tannin, or the tanning principle, is found in the bark of trees, and all those parts of vegetables which are called astringent. It has the property of forming a compound with gelatine or animal jelly that is solid, elastic, and insoluble in water. On its combination in this manner with the gelatinous part of skin, depends the art of tanning or making leather. See CUTIS.

13. Woody fibre constitutes the basis of wood. It may be procured separate from every other substance, by boiling wood shavings in water to dissolve the extractive matter, and then in alcohol to separate the resins, &c. It is insipid, insoluble in water, and combustible. When heated without access of air, it is converted into charcoal, which has been already described.

14. Colouring matter is found in vegetables combined with, 1. the extractive principle; 2. with resin; 3. with fecula; 4. gum.

The greater part of the colouring matters have a great affinity for many of the earths, but chiefly for alumina; also for the white metallic oxyds, particularly oxyd of tin; and also for animal fibrous matters, and for oxygen. On these properties, and the method of transferring the colouring principle of one body to another so that it shall be durably fixed, depends the whole art of dyeing. See DYEING.

15. Acids. The acids which exist ready formed in vegetables, are the citric, malic, oxalic, gallic, benzoic, tartaric, acetic, and suberic. They have been already described.

16. Besides the substances already enumerated, many others are found in vegetables, such as sulphur, iron, manganese, lime, alumina, magnesia, barytes, &c. All the vegetables of the class called gramina, or grasses, have an epidermis or outer skin, composed of silex. This is particularly observable in canes, which, when struck together in the dark, produce sparks of fire.

Vinous fermentation.—If mucilaginous saccharine vegetable substances, under a proper combination of water and heat (from 60 to 70° Fahrenheit), are not entirely excluded from air, they experience in a very short time a striking change in their mixture. An internal commotion takes place; the mass grows turbid; a large quantity of air bubbles are discharged from its inner part, which on account of the toughness of the matter wherein they are enclosed, form a stratum on the surface of the fluid, known by the name of yeast. These air bubbles consist of carbonic acid gas. After a time these appearances cease; the fermented liquor becomes clear and transparent, and no more gas is disengaged. The liquor now has lost its sweetness and viscidity, and has acquired the vinous taste and intoxicating quality. Wine is made in this matter from the juice of the grape; if the fermentation is checked when at its height, by excluding the air, the wine begins to ferment anew, and effervesce when again exposed to it. The sparkling wines, as champaign, are prepared in this manner, and hence should be considered as imperfect wines. Not only the juice of the grape, but all mucilaginous substances containing sugar, are capable of the vinous fermentation.

To understand these phenomena it must be observed that alcohol, which is the essence of a vinous fluid, consists of the same principles as sugar, only combined in different proportions. Alcohol contains more hydrogen and less carbon and oxygen. In the process of fermentation, therefore, a considerable part of the oxygen combines with the carbon which the saccharine fluid contains. These two form the carbonic acid gas which is expelled in the process; and the quantities of these being lessened, and the hydrogen left behind, this very essential change is effected in the liquor.

To prepare vinous liquors from grain or corn, they are converted into malt: by this process, the gluten which forms the germ is separated, and the fecula appears to be converted into sugar by the germination of the seed. From malt, beer is made by extraction and fermentation. If wine, beer, or any other fermented liquor, is distilled, a fluid is obtained which is colourless, of a strong heating taste, a penetrating odour, and an intoxicating property. This is alcohol, ardent spirit, or spirit of wine. In this state it contains a quantity of water. If this alcohol is re-distilled, and reduced to two-thirds, it is obtained very pure, and is called rectified alcohol. Alcohol is very inflammable and volatile; it dissolves resins, essential oils, camphor, sulphur, phosphorus, &c. It is composed of hydrogen, carbon, and a small quantity of oxygen. Strong acids and alcohol have a considerable re-action on each other; and this produces ether, which is a very volatile, inflammable, odorous fluid. Nitric acid with alcohol produces nitric æther, and sulphuric acid with alcohol produces sulphuric æther. See FERMENTATION.

Acetous fermentation.—When wine, or any fermented vinous liquor is exposed to a heat, from 75° to 85° Fahrenheit, and access of air is permitted, the fluid becomes turbid, and a new change of principles takes place. It loses its taste and smell, it becomes sour, and is converted into vinegar. Though vinegar is chiefly prepared from fluids which have undergone the vinous fermentation, yet this is not necessary to the production of vinegar; for simple mucilage is capable of passing into the state of acetous fermentation. When the saccharine principle predominates in any substance exposed to the necessary conditions of fermentation, alcohol is produced. When mucilage is most abundant, vinegar or acetous acid is the

product; and when gluten is most predominant, ammonia will be discovered, and putrefaction or the putrid fermentation will take place.

The process of the acetous fermentation is still more simple than that of the vinous, and consists merely in the fluid imbibing the oxygen from the atmosphere, for which it has a strong attraction; and by the access of which to the point of saturation, it is converted into an acid.

Putrid fermentation.—This is the last change, or final decomposition, of vegetables. Without moisture, heat, and a due access of air, this does not take place. In this state of fermentations ammonia is formed, accompanied by a very offensive smell. Vegetables which contain albuminous matter and gluten, are most liable to putrefaction.

Animal substances.—The constituent principles of animal substances are nearly the same with those of vegetables; but the former contain much more nitrogen and phosphorus, and the latter more carbon and hydrogen.

The proximate constituent parts of animal substances, or simple combinations of the above-mentioned radicals, are the following:

1. Gelatine, or animal jelly, is very generally dispersed through all the parts of animals, even in bones, but exists in the greatest quantity in the tendons, membranes, and the skin. It is a mucous substance, very soluble in warm water, but not in alcohol; insipid, and without smell; when cold, it congeals to a cohesive, tremulous substance. It forms the basis of soups, broths, &c. and imparts to them their nutritious qualities. When evaporated to dryness, it forms portable soup, glue, isinglass, &c. The union of this substance in the skin with tannin constitutes leather.

2. Fibrin, or animal fibre, forms the basis of the muscular, or fleshy parts of animals. It is fibrous in its structure, transparent, insoluble in water and alcohol except by a long-continued heat in a digester. It coagulates by the mere contact of air, and in a temperature of 120°, in which it differs from albumen, and also by its insolubility in cold liquid ammonia. It is soluble in acids and alkalis; by its union with the latter soap is formed. Chaptal employed this property to make soap from wool. With nitric acid it affords more nitrogen gas than any other substance. Pure fibrin may be obtained by washing away all the other parts from muscular fibre. It is very analogous to vegetable gluten.

3. Albumen is the principal constituent part of the serum of blood, and is also called coagulable lymph. The white of eggs consists almost entirely of albumen. It is insoluble in hot or cold water, oils, or alcohol; and coagulates by a heat of 160° Fahrenheit, into a white solid mass, also by acids, oxyds, and alcohol. The coagulum is only soluble in alkalis. See ALBUMEN.

4. Animal oil differs from the vegetable oils, in being generally solid at the temperature of the atmosphere, but is very similar to them in its other properties. It contains more oxygen, and also sebacic acid. Among animal oils may be ranked fat, tallow, lard, suet, butter, &c. Fish oil is generally more liquid than other animal oils. Spermaceti is an animal oil, found in the head of a species of whale. Animal fibre may be converted into a substance resembling spermaceti, by treatment with the nitric acid, and also by exposing it to a current of water for several months.

5. Bones consist chiefly of phosphate of lime, with carbonate of lime and gelatine.

6. Blood, when suffered to rest, separates into two parts; the one a coagulum or clot, called the crassamentum; the other a fluid called the serum. The crassamentum consists of fibrin, mixed with albumen or lymph, and colouring matter. The fibrin may be separated from the albumen and colouring part, by washing. The colouring part contains much iron, in an oxydated state, owing to the oxygen it receives in its passage through the lungs. The serum consists of albumen and gelatine, mixed with muriate and carbonate of soda, and phosphate of lime. It is coagulable by heat, the acids, and alcohol.

7. Milk, if suffered to rest, throws up on its surface a butyraceous oil, cream. If the remaining skimmed-milk is suffered to remain, it becomes sour, and separates into two parts; a curd, which is chiefly albumen; and whey, which is nearly analogous to serum, mixed with sugar and lactic acid. It may be made to pass into the vinous fermentation. Milk may be separated into its constituent parts, by the addition of acids and neutral salts. By the addition of rennet (which is the stomach of a calf, in which the milk has soured), milk is separated into curd and whey. Of the former cheese is made, by pressing and drying it. By agitating milk, the oily part of the cream is separated in a more solid form, constituting butter. This is also prepared by agitating the cream alone, which separates the butter from the rest of the milk which remains, called butter-milk.

8. Nails, horns, hoofs, and quills, resemble coagulated albumen.

The animal acids and phosphorus have been already described. Many other animal substances, such as bile, urine, saliva, &c. are very complicated, and but imperfectly known.

Of putrefaction.—Every animal body, when deprived of life, and exposed to the air, undergoes a decomposition, or resolution of its parts. Its colour becomes pale, then changes to blue and green; the parts become soft, and send out a fetid smell, arising from the disengagement of a very noxious gas. The organization is destroyed, and the constituent parts of the animal substance form new arrangements, and are chiefly resolved into the gaseous state. What remains is a dry powder, consisting of a mixture of earths and charcoal.

TABLE I. Of compound oxydable and acidifiable bases.

	Names of the radicals.	
Oxydable or acidifiable hydro-carbonous or carbono-hydrous radicals from the vegetable kingdom.	Tartaric	Radicals.
	Malic	
	Citric	
	Oxalic	
	Acetic	
	Succinic	
	Benzoic	
	Camphoric	
	Gallic	
	Suberic	
Oxydable or acidifiable radicals from the animal kingdom, which mostly contain azote.	Lactic	
	Saccholactic	
	Sebacic	
	Prussic	
	Laccic	
Carbono-hydrous radical from the mineral kingdom.	Mellitic	

TABLE II. Of the binary combinations of oxygen with simple substances.

	Names of the simple substances.	First degree of oxygenation.	Second degree of oxygenation.	Third degree of oxygenation.	Fourth degree of oxygenation.
Combinations of oxygen with simple non-metallic substances.	Caloric	Oxygen gas			
	Hydrogen	Water*			
	Azote	Nitrous oxyd	Nitric oxyd, or base of nitrous gas	Nitrous acid	Nitric acid
	Carbon	Charcoal or carbonous oxyd	Carbonic oxyd	Carbonic acid	
	Sulphur	Oxyd of sulphur	Sulphurous acid	Sulphuric acid	
	Phosphorus	Oxyd of phosphorus	Phosphorous acid	Phosphoric acid	
	Muriatic radical	- - - -	Muriatic acid	Muriatic acid	Hyperoxymuriatic acid
	Fluoric radical	- - - -	Fluoric acid		
	Boracic radical	Boracic oxyd	Boracic acid		
Combinations of oxygen with the simple metallic substances.	Antimony	Grey oxyd of antimony	White oxyd of antimony		
	Silver	Oxyd of silver			
	Arsenic	Grey oxyd of arsenic	White oxyd of arsenic	Arsenic acid	
	Bismuth	Grey oxyd of bismuth	White oxyd of bismuth		
	Cobalt	Grey oxyd of cobalt			
	Copper	Brown oxyd of copper	Blue and green oxyds of copper		
	Tin	Grey oxyd of tin	White oxyd of tin		
	Iron	Black oxyd of iron	Yellow and red oxyds of iron		
	Manganese	Black oxyd of manganese	White oxyd of manganese		
	Mercury	Black oxyd of mercury	Yellow and red oxyds of mercury		
	Molybdena	Oxyd of molybdena	- - - -	Molybdic acid	
	Nickel	Oxyd of nickel			
	Gold	Yellow oxyd of gold	Red oxyd of gold		
	Platina	Yellow oxyd of platina			
	Lead	Grey oxyd of lead	Yellow and red oxyds of lead		
	Tungstein	Oxyd of tungstein	- - - -	Tungstic acid	
	Zinc	Grey oxyd of zinc	White oxyd of zinc		

TABLE III. Of the combinations of oxygen with the compound radicals.

Names of the radicals.	Names of the resulting acids.
Tartaric	Tartaric acid
Malic	Malic acid
Citric	Citric acid
Oxalic	Oxalic acid
Acetic	Acetic acid
Succinic	Succinic acid
Benzoic	Benzoic acid
Camphoric	Camphoric acid
Gallic	Gallic acid
Suberic	Suberic acid
Lactic	Lactic acid
Saccholactic	Saccholactic acid
Sebacic	Sebacic acid
Prussic	Prussic acid
Laccic	Laccic acid
Mellitic	Melitic acid.

TABLE IV. Of the binary combinations of azote with the simple substances.

Simple substances.	Results of the combinations.
Caloric	Azotic gas
Hydrogen	Ammoniac

Simple substances.	Results of the combinations.
Oxygen	Nitrous oxyd Nitric oxyd Nitrous acid Nitric acid
Charcoal	This combination is hitherto unknown; should it ever be discovered, it will be called, according to the principles of our nomenclature, azuret of charcoal. Charcoal dissolves in azotic gas, and forms carbonated azotic gas
Phosphorus	Azuret of phosphorus. Still unknown
Sulphur	Azuret of sulphur. Still unknown. We know that sulphur dissolves in azotic gas, forming sulphurated azotic gas
Compound radicals	Azote combines with charcoal and hydrogen, in the compound oxydable and acidifiable bases, and is generally contained in the radicals of the animal acids
Metallic substances	Such combinations are hitherto unknown; if ever discovered, they will form metallic azurets, as azuret of gold, of silver, &c.

* Only one degree of oxygenation of hydrogen is hitherto known.

Lime, Magnesia, Barytes, Argill, Potash, Soda	Entirely unknown. If ever discovered, they will form azuret of lime, azuret of magnesia, &c.

TABLE V. Of the binary combinations of hydrogen with simple substances.

Simple substances.	Resulting compounds.
Caloric	Hydrogen gas
Azote	Ammoniac
Oxygen	Water
Sulphur	Hydruret of sulphur, or sulphuret of hydrogen
Phosphorus	Hydruret of phosphorus, or phosphuret of hydrogen
Charcoal	Hydro-carbonous, or carbono-hydrous radicals
Metallic substances, as iron, &c.	Metallic hydrurets, as hydruret of iron, &c.

These combinations take place in the state of gas, and form respectively, sulphurated and phosphorated oxygen gas.

TABLE VI. Of the binary combinations of sulphur with simple substances.

Simple substances.	Resulting compounds.
Caloric	Sulphuric gas
Oxygen	Oxyd of sulphur, Sulphurous acid, Sulphuric aid
Hydrogen	Sulphuret of hydrogen
Azote	azote
Phosphorus	phosphorus
Charcoal	charcoal
Antimony	antimony
Silver	silver
Arsenic	arsenic
Bismuth	bismuth
Cobalt	cobalt
Copper	copper
Tin	tin
Iron	iron
Manganese	manganese
Mercury	mercury
Molybdena	molybdena
Nickel	nickel
Gold	gold
Platina	platina
Lead	lead
Tungstein	tungstein
Zinc	zinc
Potash	potash
Soda	soda
Ammoniac	ammoniac
Lime	lime
Magnesia	magnesia
Barytes	barytes
Argill	argill.

TABLE VII. Of the binary combinations of phosphorus with the simple substances.

Simple substances.	Resulting compounds.
Caloric	Phosphoric gas
Oxygen	Oxyd of phosphorus, Phosphorous acid, Phosphoric acid
Hydrogen	Phosphuret of hydrogen
Azote	Phosphuret of azote
Sulphur	Phosphuret of sulphur
Charcoal	Phosphuret of charcoal
Metallic substances.	Phosphurets of metals
Potash, Soda, Ammoniac, Lime, Barytes, Magnesia, Argill	Phosphuret of potash, soda, &c.

TABLE VIII. Of the binary combinations of carbon.

Simple substances.	Resulting compounds.
Oxygen	Oxyd of charcoal or carbonous oxyd, Carbonic oxyd, Carbonic acid
Sulphur	Carburet of sulphur
Phosphorus	Carburet of phosphorus
Azote	Carburet of azote
Hydrogen	Carbono-hydrous radicals, Fixed and volatile oils
Metallic substances.	Carburets of metals
Alkalies and earths	Carburet of potash, &c.

TABLE IX. Of the combinations of azote or nitrogen in the state of nitrous acid with the salifiable bases, arranged according to the affinities of these bases with the acid.

Names of the bases.	Names of the neutral salts.	Notes.
Barytes	Nitrate of barytes	These salts are only known of late, and have received no particular name in the old nomenclature.
Potash	potash	
Soda	soda	
Lime	lime	
Magnesia	magnesia	
Ammoniac	ammoniac	
Argill	argill	
Oxyd of zinc	zinc	As metals dissolve both in nitrous and nitric acids, metallic salts must of consequence be formed having different degrees of oxygenation. Those wherein the metal is least oxygenated must be called nitrites, when more so,
iron	iron	
manganese	manganese	
cobalt	cobalt	
nickel	nickel	
lead	lead	
tin	tin	
copper	copper	

Oxyd of bismuth	Nitrate of bismuth	nitrats; but the limits of this distinction are difficultly ascertainable. The older chemists were not acquainted with any of these salts.
antimony	antimony	
arsenic	arsenic	
mercury	mercury	

silver, gold, platina } It is extremely probable that gold, silver, and platina, form only nitrats, and cannot subsist in the state of nitrites.

TABLE X. Of the combinations of azote, completely saturated with oxygen, in the state of nitric acid, with the salifiable bases, in the order of the affinity with the acid.

Bases.	Names of the resulting neutral salts.
Barytes	Nitrate of barytes
Potash	potash
Soda	soda
Lime	lime
Magnesia	magnesia
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
mercury	mercury
silver	silver
gold	gold
platina	platina.

TABLE XI. Of the combinations of sulphuric acid with the salifiable bases, in th order of affinity.

Names of the bases.	Resulting compounds.
Barytes	Sulphat of barytes
Potash	potash
Soda	soda
Lime	lime
Magnesia	magnesia
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
Oxyd of arsenic	Sulphat of arsenic
mercury	mercury
silver	silver
gold	gold
platina	platina.

TABLE XII. Of the combinations of the sulphurous acid with the salifiable bases, in the order of affinity.

Names of the bases.	Names of the neutral salts.
Barytes	Sulphite of barytes
Potash	potash
Soda	soda
Lime	lime
Magnesia	magnesia
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
mercury	mercury
silver	silver
gold	gold
platina	platina.

TABLE XIII. Of the combinations of phosphorous and phosphoric acids, with the salifiable bases, in the order of affinity.

Names of the bases.	Names of the neutral salts formed by	
	Phosphorous acid,	Phosphoric acid,
	Phosphites of	Phosphats of
Lime	lime	lime
Barytes	barytes	barytes
Magnesia	magnesia	magnesia
Potash	potash	potash
Soda	soda	soda
Ammoniac	ammoniac	ammoniac
Argill	argill	argill
Oxyd of zinc	zinc	zinc
iron	iron	iron
manganese	manganese	manganese
cobalt	cobalt	cobalt
nickel	nickel	nickel
lead	lead	lead
tin	tin	tin
copper	copper	copper
bismuth	bismuth	bismuth
antimony	antimony	antimony
arsenic	arsenic	arsenic
mercury	mercury	mercury
silver	silver	silver
gold	gold	gold.

TABLE XIV. Of the combinations of carbonic acid with the salifiable bases, in the order of affinity.

Names of the bases.	Resulting neutral salts.
Barytes	Carbonate of barytes
Lime	lime
Potash	potash
Soda	soda
Magnesia	magnesia
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
mercury	mercury
silver	silver
gold	gold
platina.	platina.

TABLE XV. Of the combinations of muriatic acid with the salifiable bases, in the order of affinity.

Names of the bases.	Resulting neutral salts.
Barytes	Muriat of barytes
Potash	potash
Soda	soda
Lime	lime
Magnesia	magnesia
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	smoking of tin solid of tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
mercury	sweet of mercury corrosive of mercury
silver	silver
gold	gold
platina	platina.

TABLE XVI. Of the combinations of oxygenated muriatic acid with the salifiable bases, in the order of affinity.

Names of the bases.	Names of the neutral salts.
Barytes	Oxygenated muriate of barytes
Potash	potash
Soda	soda
Lime	Oxygenated muriate of lime
Magnesia	magnesia
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
mercury	mercury
silver	silver
gold	gold
platina	platina.

TABLE XVII. Of the combinations of fluoric acid with the salifiable bases, in the order of affinity.

Names of the bases.	Names of the neutral salts.
Lime	Fluat of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Oxyd of zinc	zinc
manganese	manganese
iron	iron
lead	lead
tin	tin
cobalt	cobalt
copper	copper
nickel	nickel
arsenic	arsenic
bismuth	bismuth
mercury	mercury
silver	silver
gold	gold
platina	platina.
And by the dry way,	
Argill	Fluat of argill.

TABLE XVIII. Of the combinations of boracic acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Lime	Borat of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Oxyd of zinc	zinc
iron	iron
lead	lead
tin	tin
cobalt	cobalt
copper	copper
nickel	nickel
mercury	mercury
Argill	argill.

TABLE XIX. Of the combinations of arseniac acid with the salifiable bases, in the order of affinity.

Bases:	Neutral salts.
Lime	Arseniat of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Oxyd of zinc	zinc
manganese	manganese
iron	iron
lead	lead
tin	tin
cobalt	cobalt
copper	copper
nickel	nickel
bismuth	bismuth
mercury	mercury
antimony	antimony
silver	silver
gold	gold
platina	platina
Argill	argill.

TABLE XX. Of the combinations of tungstic acid with the salifiable bases.

Bases.	Neutral salts.
Lime	Tungstat of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Argill	argill
Oxyd of antimony, &c.	antimony, &c.

TABLE XXI. Of the combinations of tartaric acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Lime	Tartrite of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
silver	silver
mercury	mercury
gold	gold
platina	platina.

TABLE XXII. The malic acid combines with the salifiable bases, forming with

Potass	Malat of potass
Soda	soda
Ammonia	ammonia
Barytes	barytes
Strontian	strontian
Lime	lime
Magnesia	magnesia
Alumina	alumina.

The order of affinity is unknown.

TABLE XXIII. Of the combinations of citric acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Barytes	Citrat of barytes
Lime	lime
Magnesia	magnesia
Potash	potash
Soda	Soda
Ammoniac	ammoniac
Oxyd of zinc	zinc
manganese	manganese
iron	iron
lead	lead
cobalt	cobalt
copper	copper
arsenic	arsenic
mercury	mercury
antimony	antimony
silver	silver
gold	gold
platina	platina
Argill	argill.

TABLE XXIV. Of the combinations of the suberic acid with the salifiable bases, in the order of affinity.

Names of the bases.	Names of the neutral salts.
Barytes	Suberat of barytes
Potass	potass
Soda	soda
Lime	lime
Ammonia	ammonia
Magnesia	magnesia
Alumina	alumina.

TABLE XXV. Of the combinations of the oxalic acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Lime	Oxalat of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
copper	copper

Oxyd of bismuth	Oxalat of bismuth
antimony	antimony
arsenic	arsenic
mercury	mercury
silver	silver
gold	gold
platina	platina.

TABLE XXVI. Of the combinations of acetic acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Barytes	Acetat of barytes
Potash	potash
Soda	soda
Lime	lime
Magnesia	magnesia
Ammoniac	ammoniac
Oxyd of zinc	zinc
manganese	manganese
iron	iron
lead	lead
tin	tin
cobalt	cobalt
copper	copper
nickel	nickel
arsenic	arsenic
bismuth	bismuth
mercury	mercury
antimony	antimony
silver	silver
gold	gold
platina	platina
Argill	argill.

TABLE XXVII. Of the combinations of succinic acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Barytes	Succinat of barytes
Lime	lime
Potash	potash
Soda	soda
Ammoniac	ammoniac
Magnesia	magnesia
Argill	argill
Oxyd of zinc	zinc
iron	iron
manganese	manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
mercury	mercury
silver	silver
gold	gold
platina	platina.

TABLE XXVIII. Benzoic acid combines

with	forming
Barytes	Benzoat of barytes
Lime	lime
Potass	potass
Soda	soda
Ammonia	ammonia
Magnesia	magnesia
Alumina	alumina.

Order of affinity unknown.

TABLE XXIX. Camphoric acid combines

with	forming
Lime	Camphorat of lime
Potass	potass
Soda	soda
Barytes	barytes
Ammonia	ammonia
Magnesia	magnesia
Alumina	alumina.

TABLE XXX. Lactic acid combines

with	forming
Potass	Lactat of potass
Soda	soda
Ammonia	ammonia
Barytes	barytes
Lime	lime
Alumina	alumina
Magnesia	magnesia.

TABLE XXXI. Of the combinations of saccholactic acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Lime	Saccholat of lime
Barytes	barytes
Magnesia	magnesia
Potash	potash
Soda	soda
Ammoniac	ammoniac
Argill	argill
Oxyd of zinc	zinc
manganese	manganese
iron	iron
lead	lead
tin	tin
cobalt	cobalt
copper	copper
nickel	nickel
arsenic	arsenic
bismuth	bismuth
mercury	mercury
antimony	antimony
silver	silver.

TABLE XXXII. Of the combinations of the prussic acid with the salifiable bases, in the order of affinity.

Bases.	Neutral salts.
Potash	Prussiat of potash
Soda	soda
Ammoniac	ammon
Lime	lime
Barytes	barytes
Magnesia	magnesia
Oxyd of zinc	zinc
iron	from

Oxyd of manganese	Prussiat of manganese
cobalt	cobalt
nickel	nickel
lead	lead
tin	tin
copper	copper
bismuth	bismuth
antimony	antimony
arsenic	arsenic
silver	silver
mercury	mercury
gold	gold
platina	platina.

TABLE XXXIII. Mellitic acid combines

with	forming
Potass	Mellat of potass
Soda	soda
Ammonia	ammonia
Lime	lime
Barytes	barytes
Alumina	alumina.

The combinations of the remaining acids with the salifiable bases are for the most part unknown; when ascertained they will be denominated from their constituent acids as follows:

From the Sebacic acid	Sebats
Laccic acid	Laccats
Gallic acid	Gallats.

GLOSSARY OF CHEMICAL TERMS.

Affinity, the same with elective attraction (see the article ATTRACTION), means that attraction which exists between the very minute particles of bodies. It is essentially different from the attraction of gravitation, since it is not governed by the masses or specific gravity of the particles. It has been termed elective attraction, because something analogous to preference or choice may be observed in this kind of action of bodies on each other. Thus, spirit of wine will dissolve resin, but water will not; on the contrary gum will dissolve in water, while it is insoluble in spirit. Nay, some fluids will let fall the particles of certain bodies, in order to take up and combine with those of others. Thus, if a quantity of silver is added to aqua-fortis (nitric acid), the cohesion of the particles of silver will be destroyed, and they will unite forcibly with those of the aqua-fortis. The fluid will remain perfectly clear, because the particles even in this state of combination, are so extremely minute that the rays of light will suffer no interruption in passing through them. If however, to this solution of silver, a quantity of mercury is added, the aqua-fortis will be attracted by the mercury, and the silver will be thrown down or precipitated to the bottom of the vessel in which the fluid is contained. (Hence the chemical term precipitation.) If again copper is added, it will assume the place of the mercury, which of course in its turn will be precipitated. If to this solution of copper, a piece of bright iron (for rust would prevent the action of the acid) is introduced, the surface of the iron will be dissolved, and the copper precipitated, and will be deposited on the bar of iron. The iron may afterwards be precipitated by the introduction of an alkali. On this principle are founded the tables of affinity or elective attraction, which state the substances in order as they have an attraction for each other. It is a general maxim in chemistry, that for bodies to act in this manner on each other, one of them must be in a fluid state. A double elective attraction or affinity is, when two bodies, each compounded of two principles, mutually change a principle of each. Thus, when the salt which is compounded of mercury with nitric acid is presented to a solution of vitriolated tartar, the vitriolic acid will quit the alkali, and unite with the mercury, and the nitric acid will combine with the alkali. This is also sometimes called the attraction of combination.

Calcination, applied to the metals, is their oxygenation by means of heat.

Concentration, the separation and evaporation by means of heat of the watery particles from any fluid; by which the fluid is said in common language to become stronger, or less diluted.

Crucible, a vessel usually made of clay, employed as a melting-pot for metals or other substances.

Crystallization, is when a body passing from a fluid to a solid state, assumes a regular form. See the article CRYSTALLIZATION.

Decantation, the separation of a fluid from the solid concrete particles which it contains. This is done by leaving the fluid at rest in a conical vessel, when the foreign matter will deposit itself at the bottom, and if the fluid is very gently poured off it will be obtained tolerably clear. A syphon is sometimes employed with advantage when the matter deposited is light, and there is danger of shaking the vessel. A thick woollen thread steeped in the liquor, and inclining over the edge of the vessel into another, makes a very good syphon for this purpose.

Decoction is the extracting, by the application of heat and moisture, of some portion of matter from certain substances, as the gums and essential oils from vegetables. When the extract is made in cold water it is called infusion.

Decrepitation, the small and successive explosions which take place when salts are exposed to heat to expel their water of crystallization.

Desiccation (drying), the expelling or evaporating humid matter from any substance by means of heat.

Detonation, an explosion caused by the sudden expansion of certain substances, when either a very rapid combination or decomposition takes place.

Digestion, the slow action of a solvent upon any substance, often assisted by the heat of a sand-bath.

Distillation, the operation which by means of heat and moisture separates volatile matters from those which are fixed, or matters more or less volatile from one another.

Effervescence, the escape of volatile matters from the mass of a fluid, which in their passage through cause a kind of ebullition.

Efflorescence. When solid or consistent bodies spontaneously become converted into powder, the surface ap-

pears covered with a white dust. This effect is occasioned by the loss of the water of crystallization.

Extract, the solid matter left behind when the watery parts are evaporated from a decoction or infusion.

Fixed, an epithet descriptive of such bodies as resist the action of heat, so as not to rise in vapour. It is opposed to volatile.

Fulmination, a still more violent and sudden explosion than detonation.

Fusion, the passing of a solid body to a fluid state by means of heat.

Infusion, the extraction of resinous, gummy, or other matters, by the action of water in the common temperature of the atmosphere.

Lixiviation, the process of separating by solution in water those matters which are soluble in any body from those which are insoluble; generally applied to the fixed residues of bodies for the purpose of extracting the saline parts, which dissolve in the water, and afterwards crystallize on evaporation.

Mixture, the aggregation or mechanical union of bodies which have no affinity or chemical combination. It is opposed to solution, where the particles of the fluid and solid body are permanently combined. In mere mixtures, when set at rest, one part will commonly subside and form a sediment.

Oxidation, the combination of any other body with oxygen.

Precipitation, the effect which takes place in solution, in consequence of elective attraction, when one matter is let fall to the bottom in consequence of the fluid particles combining with another. (See Affinity, above.) The product is also called a precipitation.

Reagent, a body which is brought in contact with another to promote the separation of its principles or constituent parts. The reagents are the immediate means of precipitation.

Rectification, the further purification of matters by a second or third distillation or sublimation.

Reduction, the bringing back the oxyds or calces of metals to the pure metallic state, by expelling the oxygen, which is generally done by exposing the oxyd to the action of heat along with some matter containing carbon; when the oxygen and carbon go off in the form of carbonic acid gas, leaving the metal pure.

Residuum (formerly called caput-mortuum), that part of a body which remains after a part has been separated by an operation, such as distillation or sublimation.

Saturation. Most bodies that have a chemical affinity for each other will only unite in certain proportions. When, therefore, a fluid has dissolved as much of any substance as it will dissolve, it is said to have reached the point of saturation. Thus, water will dissolve one quarter of its weight of common salt; and if more is added, it will sink to the bottom in a solid state. Some fluids will dissolve more of certain substances when hot than when cold. Thus water when hot will dissolve a much larger quantity of nitre than when cold.

Solution, the dispersion of the particles of a solid body in any fluid in so equal a manner, that the compound liquor shall be perfectly and permanently clear and transparent. This happens when the particles of the fluid have an affinity or elective attraction for the particles of the solid. When solid particles are only dispersed in a fluid by mechanical means, it is mixture, and the compound is commonly opaque and muddy.

Sublimation is to dry matters what distillation is to humid ones. It is the process by which the volatile are separated from the fixed parts of bodies by the application of heat alone without moisture.

Vitrification, the convertion into glass of such substances as are capable of assuming that form.

Volatilization, the reducing into vapour such substances as are capable of assuming that state.

CHENOLEA, a genus of the order monogynia, in the pentandria class of plants. The calyx is globular, one-leafed, five-parted; caps. one-celled, with one smooth seed. There is one species, a native of the Cape.

CHENOPODIUM, *goose-foot*, or *wild orach*, a genus of the digynia order, in the pentandria class of plants, and in the natural method ranking under the 12th order, holoraceæ. The calyx is pentaphyllous and pentagonal; no corolla; one seed, lenticular, superior. There are 23 species, 13 of which are natives of Britain. Most of them have an aromatic smell. A species which grows near the Mediterranean is used by the Egyptians in sallads, on account of its saltish aromatic taste. From this plant kelp is made in other countries. The most remarkable are:

1. Chenopodium ambrosoides, or the oak of Cappadocia. These are easily propagated from seeds, and thrive best in a rich soil.

2. Chenopodium bonus Henricus, or common English mercury, found growing naturally in shady lanes in many places in Britain. It was formerly used as spinach, but is now disused, being greatly inferior. As an article of the materia medica, it is ranked among the emollient herbs, but rarely used in practice. The leaves are applied by the country-people for healing slight wounds, cleansing old ulcers, and the like purposes. The roots are given to sheep that have a cough. Goats and sheep are not fond of the herb; cows, horses, and swine, refuse it.

3. Chenopodium botrys, or the oak of Jerusalem, like that of Cappadocia, thrives best in a rich light earth, and may be easily propagated from seeds, as indeed all the other species may.

4. Chenopodium scoparia, the belvidere, or annual mock cypress, is an ornamental plant. It is eaten in China.

CHERLERIA, a genus of the decandria trigynia class of plants. The flower has properly no petals; the nectaria are five in number, roundish and emarginated, very small, and placed in a circular direction. The fruit is a capsule, formed of three valves, and containing three seeds. There is one species.

CHERMES, in zoology, a genus of insects belonging to the order hemiptera. The rostrum is situated on the breast; the feelers are longer than the thorax: the four wings are deflected: the thorax is gibbous; and the feet are of the jumping kind. There are 17 species. It is an insect to be met with in great numbers upon the fig-tree. The larva has six feet. It is like the insect, when provided with wings. Its form is oblong, and its motion

is slow. The chrysalis differs from it by two flat buds that spring from the thorax, and inclose the wings, afterwards seen in the perfect insect. These chrysalids are frequently met with on plants; and the two plates of their thorax give them a broad uncouth appearance, and a heavy look. When the little chrysalids are going to be metamorphosed, they remain motionless under some leaves upon which they fix themselves. Their skin then divides upon the head and thorax, and the perfect insect comes forth with his wings. The perfect insect is furnished with four wings, large in proportion to its body. Several species are provided at the extremity of their body with a small sharp pointed implement, but which lies concealed, and which they draw out in order to deposit their eggs, by making a puncture in the plant that suits them. By this method the fir-tree chermes produces that enormous scaly protuberance which is to be found at the summit of the branches of that tree, and which is formed by the extravasation of the juices occasioned by the punctures. The young larvæ shelter themselves in cells contained in the tumour. The white down, under which the larva of the pine-chermes is found, seems to be produced much in the same manner. That of the box-tree chermes produces no turbercula like those; but its punctures make the leaves of that tree bend and grow hollow in the shape of a cap, which, by the union of those inflected leaves, produces at the extremity of the branches a kind of knobs, in which the larvæ of that insect find shelter. The box chermes, as well as some others, has yet another peculiarity, which is, that the larva and its chrysalis eject at the anus a white sweet-tasted matter, that softens under the touch, and is not unlike manna. This substance is found in small white grains within the balls formed by the box-leaves, and a string of the same matter is often seen depending from the anus of the insect.

CHERT, among miners, denotes a kind of flinty stone, found in thin strata in quarries of lime-stone. This stone is usually amorphous, occurring sometimes in mass, sometimes in round balls. Its specific gravity is from 2.699 to 2.708; colour usually greyish blue, but it sometimes is found grey, blue, green, and brown of different shades. Different colours frequently appear in the same specimen. It is called by Kirwan, hornstone, and by him it is said to consist of

72 parts of silica
22 ——— alumine
6 ——— carbonate of lime.

100.

CHESS, an ingenious game, performed with different pieces of wood, on a board divided into 64 squares or houses, in which chance has so small a share, that it may be doubted whether a person ever lost but by his own fault. Each gamester has eight dignified pieces, viz. a king, a queen, two bishops, two knights, and two rooks, also eight pawns; all which, for distinction sake, are painted of two different colours, as white and black.

As to their disposition on the board, the white king is to be placed on the fourth black house from the corner of the board, in the first and lower rank; and the black king is to be placed on the fourth white house on the opposite or adversary's end of the board. The queens are to be placed next to the kings, on houses of their own colour. Next to the king and queen, on each hand, place the two bishops; next to them the two knights; and last of all, on the corners of the board, the two rooks. As to the pawns, they are placed without distinction on the second rank of the house, one before each of the dignified pieces.

Having thus disposed the men, the onset is commonly begun by the pawns, which march straight forward in their own file, one house at a time, except the first move, when it can advance two houses, but never moves backwards. The manner of their taking the adversary's men is sideways, in the next house forwards; where having captivated the enemy, they move forward as before. The rook goes forward or crossways through the whole file and back again. The knight skips backward and forward to the next house, save one, of a different colour, with a sidling march, or a slope, and thus kills his enemies that fall in his way, or guards his friends that may be exposed on that side. The bishop walks always in the same colour of the field that he is placed in at first, forward and backward, aslope, or diagonally, as far as he lists. The queen's walk is more universal, as she takes all the steps of the before-mentioned pieces, excepting that of the knight: and as to the king's motion, it is one house at a time, and that either forward, backward, sloping, or sideways.

As to the value of the different pieces, next to the king is the queen, after her the rooks, then the bishops, and last of all the dignified pieces comes the knight. The difference of the worth of pawns is not so great as that of noblemen; only, it must be observed, that the king's bishop's pawn is the best in the field, and therefore the skilful gamester will be careful of him. It ought also to be observed, that whereas any man may be taken, when he falls within the reach of any of the adversary's pieces, it is otherwise with the king, who, in such a case, is only to be saluted with the word *check*, warning him of his danger, out of which it is absolutely necessary that he move; and if it so happens that he cannot move without exposing himself to the like inconveniency, it is checkmate and, the game is lost.

CHIAROSCURO, effect produced in painting or drawing, by an artful conduct and union of colours and light and shade. See PAINTING.

CHIAROSCURO is also used, improperly, to express the general effect of light and shade produced in painting or drawing by the use of one tint only, as in designs executed in white and black, or white and brown, &c.

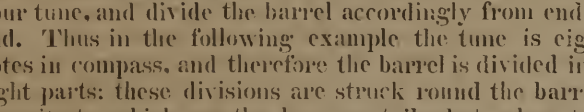
CHIEF, in heraldry, is that which takes up all the upper part of the escutcheon, from side to side, and represents a man's head.

CHILDREN, are in law a man's issue begotten on his wife. In case land is given by will to a man and his children, who has such alive, the devisee takes only an estate for life; but if there is no child living, it is held to be an estate tail. 1 Vent. 214.

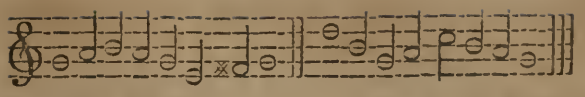
CHILIAD, denotes a thousand of any things, ranged in several divisions, each whereof contains that number.

CHILIAGON, in geometry, a regular plain figure of 1000 sides and angles. It is easily demonstrable that the sum of all the angles of such a figure is equal to 196 right ones. For the internal angles of every plane figure are

equal to twice as many right angles as the figure hath sides, except those four which are about the centre of the figure. Hence it may be resolved into as many triangles as the figure has sides.



CHILTERN HUNDREDS, *stewards of the*. Of the hundreds into which many of the English counties were divided by king Alfred for their better government, the jurisdiction was originally vested in peculiar courts; but came afterwards to be devolved to the county courts, and so remains at present; except with regard to some, as the Chilterns in Buckinghamshire, which have been by privilege annexed to the crown. These having still their own courts, a steward of those courts is appointed by the chancellor of the exchequer, with a salary of 20*s*. and all fees, &c. belonging to the office. This is made a matter of convenience to the members of parliament. When any of them wishes to resign, he accepts the stewardship of the Chiltern hundreds, which vacates his seat.



CHIMARRHIS, a genus of the class and order pentandria monogynia. The essential character is; cor. funnel-form; caps. inferior, obtuse; two-celled; two-valved; seeds one in each cell. There is one species, a lofty tree, a native of Martinico.

CHIMES *of a clock*, a kind of periodical music, produced at equal intervals of time, by means of a particular apparatus added to a clock.

In order to calculate numbers for the chimes, and adapt the chime-barrel, it must be observed that the barrel must turn round in the same time that the tune it is to play requires in singing. As for the chime-barrel, it may be made of certain bars that run athwart it, with a convenient number of holes punched in them, to put in the pins that are to draw each hammer; and these pins, in order to play the time of the tune rightly, must stand upright, or hang down from the bar, some more some less. To place the pins rightly, you may proceed by the way of changes on bells, viz. 1, 2, 3, 4; or rather make use of the musical notes. Observe what is the compass of your tune, and divide the barrel accordingly from end to end. Thus in the following example the tune is eight notes in compass, and therefore the barrel is divided into eight parts: these divisions are struck round the barrel, opposite to which are the hammer-tails; but when two notes of the same sound come together in a tune, there must be two hammers to that bell to strike it. Then you are to divide it round about, into as many divisions as there are musical bars, semibriefs, minims, &c. in your tune. Thus the hundreth Psalm tune has twenty semibriefs, the first note of it is also a semibrief, and therefore on the chime-barrel must be a whole division from 5 to 5; as may be understood by conceiving the surface of a chime-barrel to be represented by the following tables, as if the cylindrical superficies of the barrel was stretched out at length, or extended on a plane; and then such a table so dotted or divided, if it was to be wrapped round the barrel, would show the places where all the pins are to stand in the barrel: for the dots running about the table, are the places of the pins that play the tunes.

The notes of the hundreth Psalm.

A table for dividing the chime-barrel of the hundreth Psalm.

If you would have your chimes complete, you ought to have a set of bells to the gamut notes; so as that each bell having the true sound of sol, la, mi, fa, you may play any tune with its flats and sharps, nay even the bass and treble, with one barrel. And by setting the names of your bells at the head of any tune, you may transfer that tune to your chime-barrel, without any skill in music; but observe, that each line in the music is three notes distant; that is, there is a note between each line, as well as upon it.

CHIMNEY. The rules for building chimneys, in England, are, 1. That no timber be laid within twelve inches of the fore side of the chimney-jambs. 2. That all the joists on the back of any chimney be laid with a trimmer. 3. That no timber be laid within the funnel of any chimney.

CHIMNEY-SWEEPERS. The overseers, &c. of any parish, may bind any boy of the age of eight years or upwards, who is chargeable to the parish, to any person using the trade of a chimney-sweeper, till he shall attain the age of 16 years, provided that it be done with the consent of the parent of such boy. And no master shall have more than six apprentices at one time. Every master shall cause his name and place of abode to be put upon a brass plate, and to be fixed upon the front of a leathern cap, which he shall provide for each apprentice, who shall wear the same when out upon his duty; on pain of forfeiting for every such apprentice, above such number, or without having such cap, not exceeding 10*l*. nor less than 5*l*.

For an apparatus for sweeping chimneys, see MACHINES.

CHIOCOCCA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 48th order, aggregatæ. The corolla is funnel-shaped and equal; the berry unilocular, dispermous, inferior. There are two species.

CHIONANTHUS, the snow-drop, or fringe-tree, a genus of the monogynia order, belonging to the diandria class of plants, and in the natural method ranking under the 44th order, sepiariæ. The corolla is quadrifid, with the segments very long; the fruit is a plumb. There are 4 species described by botanists. The most remarkable is the

Chionanthus Virginica, common in Virginia and South Carolina, where it grows by the side of rivulets. It rises to ten feet.

CHIRONIA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking under the 20th order, rotaceæ. The corolla is wheel-shaped; the pistil declining downwards; the stamina placed in the tube of the corolla; the antheræ in their last stage spiral; the seed-case bilocular. There are 10 species, of which the most remarkable is the

Choronia fruitescens, a native of the Cape of Good Hope. The flowers are tubulous, and spread open at the top. They are of a bright red colour, and when a large number of them open on the same plant, they make a fine appearance. They are produced from June to autumn, and the seeds ripen in October.

CHIROGRAPHER OF FINES. The officer in the common pleas, who engrosses fines in that court, acknowledged into a perpetual record, after they are acknowledged and fully passed by those officers by whom they were examined, and that write or deliver the indentures of them to the party. This officer also makes two indentures, one for the buyer and another for the seller; and makes one other indented piece, containing also the effect of the fine, which he delivers over to the custos brevium.

CHIRURGERY. See SURGERY.

CHITON, a genus of the order of vermes testaceæ. The shell is plated, and consists of many parts lying upon each other transversely. The inhabitant is a species of doris. There are nine species. See Plate XXXIII. Nat. Hist. fig. 117.

CHIVALRY, a tenure of land by knight's service, whereby the tenant is bound to perform some noble or military office to his lord.

CHLORA, a genus of the monogynia order, in the octandria class of plants. The calyx is octophyllous, the corolla monopetalous and octofid; the capsule unilocular, bivalved, and polyspermous. There are four species.

CHLORANTHUS, a genus of the class and order tetrandria monogynia. The essential character is, calyx none; corolla three-lobed, petal by the side of the germ; anthers growing to the petal; drupe seeded. There is one species, a native of China.

CHLORITES, in natural history, a kind of green jasper, but almost as pellucid as the coarser emeralds. This mineral enters as an ingredient into different mountains. It is sometimes amorphous, and sometimes crystallized in oblong, four-sided, acuminated crystals. Its texture is foliated; it is opaque and green. There are four species.

1. The earthy chlorite is composed of scales scarcely cohering, either heaped together, or investing other stones. It feels greasy, gives an earthy smell when breathed on; and is difficult to pulverize. The colour is grass-green, sometimes greenish brown, or a very dark green inclining to black. When the powder of the chlorite is exposed to the blow-pipe, it becomes brown: it froths and melts into a dark-brown glass; with borax it forms a greenish-brown glass.

2. Common chlorite, texture earthy; colour dark green; streak mountain-green.

3. Foliated chlorite, colour dark green, sometimes crystallized in six-sided tubes; greasy or pearly, texture foliated.

4. Shistose chlorite, structure slaty; fragments flatted; colour greenish-grey, or dark green inclining to black; streak mountain green.

Supposing that these analyses are accurate, the difference between them shows that the chlorite is not a chemical combination, but a mechanical mixture.

CHOCOLATE, in commerce, a kind of paste, or cake, prepared chiefly from the cacao-nut.

When the cacao is properly roasted, and well cleaned, it is pounded in a mortar, to reduce it into a coarse mass, which is afterwards ground on a stone till it is of the necessary fineness: the paste being sufficiently ground, it is put hot into tin moulds, in which it congeals in a very little time. The form of these moulds is arbitrary; the cylindrical ones, holding two or three pounds, are the most proper; because the larger the cakes are, the longer they will keep. These cakes are very liable to take any good or bad scent, and therefore they must be carefully wrapt up in paper, and kept in a dry place. Complaints are made, that the Spaniards mix with the cacao-nuts too great a quantity of cloves and cinnamon, besides other drugs, as musk, ambergris, &c. The grocers of Paris use few or none of these ingredients; they only choose the best nuts, which are called caracca, from the place whence they are brought; and with these they mix a very small quantity of cinnamon, the freshest vanilla, and the finest sugar, but very seldom any cloves. In England, the chocolate is made of the simple cacao, excepting that sometimes sugar, and sometimes vanilla, is added.

Chocolate, fresh from the mill, as it cools in the tin pans into which it is received, becomes strongly electrical, and it retains this property some time after it has been turned out of the pans.

Chocolate ready made, and cacao-paste, are prohibited to be imported from any part beyond the seas. If made and sold in great Britain, it pays inland-duty 1s. 6d. per pound avoirdupois: in must be inclosed in papers containing one pound each, and produced at the excise-office, to be stamped. Upon three days notice given to the officer of excise, private families may make chocolate for their own use, provided no less than half a hundred weight of nuts are made at one time.

CHOENIX, a dry measure, containing the forty-eighth part of a medimnus, or six bushels. Hence the celebrated proverb of Pythagoras, Super chœnice ne sedeas.

CHOLERA MORBUS. See MEDICINE.

CHONDRILLA, a genus of the polygamia æqualis order, in the syngenesia class of plants: and in the natural method ranking under the 49th order, compositæ. The receptacle is naked; the calyx calyculated; the pappus simple and stalked; the florets in a manifold series. There are three species.

CHORD, in geometry, a right line drawn from one extremity of an arch of a circle to the other. See GEOMETRY.

CHORDS, *Line of*, one of the lines of the sector and plane scale. See MATHEMATICAL INSTRUMENTS.

CHORDS, or CORDS, in music, are strings, by the vibration of which the sensation of sound is excited, and by the divisions of which the several degrees of tune are determined.

To find the number of vibrations made by a musical chord, or string, in a given time, having its weight, length, and tension, given. Let l be the length of the chord in feet; 1 its weight, or rather a small weight fixed to the middle, and equal to that of the whole chord; and w the tension, or a weight by which the chord is stretched. Then the time of one vibration will be ex-

pressed by $\frac{11}{7}\sqrt{\frac{l}{32\frac{1}{6}w}}$; consequently the number of vibrations per second is equal to $\frac{7}{11}\sqrt{\frac{32\frac{1}{6}w}{l}}$. Thus, if $w = 28800$, or the tension equal to 28800 times the weight of the chord, and the length of it three feet, then the last theorem gives 354 nearly for the number of vibrations made in each second of time. But if $w = 14400$, there would be only 250 vibrations per second; and if $w = 288$, there would be $35\frac{5}{43}$ vibrations per second.

CHORIAMBUS, in ancient poetry, a foot consisting of four syllables, the first and last are long, and the two middle ones are short; or, which is the same thing, it is made up of a trochæus and iambus: such is the word nōbilitās.

CHOROGRAPHY, the art of making a map of some country or province.

Chorography differs from geography, as the description of a particular country does from that of the whole earth; and from topography, as the description of a country differs from that of a town or district.

CHOSE, *in action*, is an incorporeal thing, and only a right, as an annuity, bond, covenant, &c. and generally all causes of suit, for any duty or wrong, are accounted choses in action. Choses in action may be also called choses in suspense, as having no real existence, and not being properly in our possession.

CHRIST, order of, a military order, founded by Dionysius I. king of Portugal, to animate his nobles against the Moors.

The arms of this order are gules, a patriarchal cross, charged with another cross argent: they had their residence at first at Castromarin, afterwards they removed to the city of Thomar, as being nearer to the Moors of Andalusia and Estremadura.

CHROMATIC, in the ancient music, the second of the three kinds into which the consonant intervals were subdivided into their concinnous parts. The other kinds are enharmonic and diatonic.

CHROMATICS, that part of optics which explains the several properties of colours. See Optics.

CHRONIC, or Chronical, among physicians, an appellation given to diseases that continue a long time, in contradistinction to those that soon terminate and are called acute. See Medicine.

CHRONICLE, in matters of literature, a species or kind of history, disposed according to the order of time, and agreeing in most respects with annals. The word chronicle is now become obsolete, being seldom used except in speaking of the old English histories, as Stowe's chronicle, Holingshed's chronicle, &c.

CHRONOLOGY, the art of measuring and distinguishing time; with the doctrines of dates, epochs, æras, &c. is a science of the utmost importance for the right understanding of history. It depends and is founded on 1st, astronomical observations, especially of the eclipses of the sun and moon, combined with calculations of the year, and æras of different nations. 2dly, On the testimonies of credible authors. 3dly, Such epochs in history as have never been controverted. 4thly, Ancient medals, coins, monuments, and inscriptions.

Sir Isaac Newton has shown that the chronology of ancient kingdoms is involved in the greatest uncertainty; and that the Europeans had no chronology before the existence of the Persian empire, or 536 years before Christ, when Cyrus conquered Darius: that the antiquities of the Greeks are full of fables, till this period, and that after this time several Greek historians introduced the computation by generations.

The chronology of the Latins was still more uncertain: their old records having been burnt by the Gauls 120 years after the expulsion of their kings, and 388 before the birth of Christ. The chronologers of Gaul, Spain, Germany, Scythia, Sweden, Britain, and Ireland, are of a still later date; for Scythia beyond the Danube had no letters till Ulphilas, their bishop, formed them, about the year 276. Germany had none till it received them from the western empire of the Latins about the year 400. The Huns had none in the days of Procopius, about the year 526; and Sweden and Norway received them still later.

Sir Isaac Newton, after a general account of the obscurity and defects of the ancient chronology, observes, that though many of the ancients computed by successions and generations, yet the Egyptians, Greeks, and Latins, reckoned the reigns of kings equal to generations of men, and three of them to a hundred, and sometimes to 120 years, and this was the foundation of their technical chronology. He then proceeds, from the ordinary course of nature, and a detail of historical facts, to show the difference between reigns and generations; and that, though a generation from father to son may at an average be reckoned about 33 years, or three of them equal to 100 years, yet, when they are taken by the eldest sons, three of them cannot be estimated at more than about 75 or 80 years; and the reigns of kings are still shorter; so that 18 or 20 years may be allowed as a just medium. Sir Isaac then fixes on four remarkable periods, viz. the return of the Heraclidæ into the Peloponnesus, the taking of Troy, the Argonautic expedition, and the return of Sesostris into Egypt after his wars in Thrace; and he settles the epoch of each by the true value of a generation. To instance only his estimate of that of the Argonautic expedition: Having fixed the return of the Heraclidæ to about the 159th year after the death of Solomon, and the destruction of Troy to about the 76 year after that period, he observes, that Hercules the Argonaut was the father of Hyllus, the father of Clerdius, the father of Aristomachus, the father of Aristodemus, who conducted the Heraclidæ into Peloponnesus: so that, reckoning by the chiefs of the family, their return was four generations later than the Argonautic expedition, which therefore happened about 43 years after the death of Solomon. This is farther confirmed by another argument: Æsculapius and Hercules were Argonauts: Hippocrates was the 18th inclusively from the former by the father's side, and the 19th from the latter by the mother's side: now, allowing 28 or 30 years to each of them, the 17 intervals by the father, and the 18 intervals by the mother, will on a medium give 507 years; and these, reckoning back from the commencement of the Peloponnesian war, or the 431st year before Christ, when Hippocrates began to flourish, will place the Argonautic expedition in the 43d year after the death of Solomon, or 937 before Christ.

The other kind of reasoning by which sir Isaac Newton endeavours to establish this epoch, is purely astronomical. The sphere was formed by Chiron and Musæus for the use of the Argonautic expedition, as is plainly shown by several of the asterisms referring to that event: and at the time of the expedition the cardinal points of the equinoxes and solstices were placed in the middle of the constellations Aries, Cancer, Chelæ, and Capricorn. This point is established from the consideration of the ancient Greek calendar, which consisted of 12 lunar months, and each month of 30 days, which required an intercalary month. Of course this lunisolar year, with the intercalary month, began sometimes a week or two before or after the equinox or solstices: and hence the first astronomers were led to the before-mentioned disposition of the equinoxes and solstices: and that this was really the case, is confirmed by the testimonies of Eudoxus, Aratus, and Hipparchus. Upon these principles sir Isaac proceeds to argue in the following manner. The equinoctial colure in the end of the year 1689 cut the ecliptic in ♉ 6° 44′; and by this reckoning the equinox had then gone back 36° 44′ since the time of the Argonautic expedition. But it recedes 50″ in a year, or 1° in 72 years, and consequently 36° 44′ in 2645 years; and this, counted backwards from the beginning of 1690, will place this expedition about 25 years after the death of Solomon. But as there is no necessity for allowing that the middle of the constellations, according to the general account of the ancients, should be precisely the middle between the prima Arietis and ultima Caudæ, our author proceeds to "examine what were those stars through which Eudoxus made the colures to pass in the primitive sphere, and in this way to fix the position of the cardinal points." Now from the mean of five places he finds, that the great circle, which in the primitive sphere, described by Eudoxus, or which at the time of the Argonautic expedition, was the equinoctial colure, did in the end of 1989 cut the ecliptic in ♉ 6° 29′ 15″. In the same manner our author determines that the mean place of the solstitial colure is ♌ 6° 28′ 46″, and as it is at right angles with the other, he concludes that it is rightly drawn. And hence he infers that the cardinal points, in the interval between that expedition and the year 1689, have receded from those colures 1s. 6° 29′; which, allowing 72 years to a degree, amounts to 2627 years: and these counted backwards, as above, will place the Argonautic expedition 43 years after the death of Solomon. Our author has, by other methods also of a similar nature, established this epoch, and reduced the age of the world 500 years.

The use of chronology.—The divisions of time which are considered in chronology, relate either to the different methods of computing days, months, and years, or to the remarkable æras or epochas from which any year receives its name, and by means of which the date of any event is fixed.

Days have been very differently terminated and divided by different people in different ages, which it is of some importance to a reader of history to be acquainted with. The ancient Babylonians, Persians, Syrians, and most other eastern nations, with the present inhabitants of the Balearic islands, Greeks, began their day with the sun's rising. The ancient Athenians and Jews, with the Austrians, Bohemians, Marcomanni, Silesians, modern Italians, and Chinese, reckon from the sun's setting: the ancient Umbri and Arabians, with the modern astronomers, from noon; and the Egyptians and Romans, with the modern English, French, Dutch, Germans, Spaniards, and Portuguese, from midnight.

The Jews, Romans, and most other ancient nations, divided the day into twelve hours, and the night into four watches. But the custom which prevails in this western part of the world at present is, to divide the day into 24 equal portions: only with some the 24 are divided into twice 12 hours; whereas others, particularly the Italians, Bohemians, and Poles, count 24 hours without interruption.

Different people have made their years to begin at different times, and have used a variety of methods to give names to them, and distinguish them from one another.

The Jews began the year for civil purposes in the month of *Tizri*, which answers to our September; but for ecclesiastical purposes with *Visan*, which answers to our April, at which time they kept the passover. The Athenians began the year with the month *Hecatombæon*, which began with the first new moon after the summer solstice. The Romans had at first only ten months in their year, which ended with December; but Numa added January and February. At present there are in Rome two ways of reckoning the year. One begins at Christmas, on account of the nativity of our Saviour; and the notaries of Rome use this date, prefixing to their deeds, *a nativitate:* and the other at March, on account of the incarnation of Christ, and therefore the pope's bulls are dated *anno incarnationis.* The ancient French historians began the year at the death of St. Martin, who died in the year 401 or 402; and they did not begin in France to reckon the year from January till 1564, by virtue of an ordinance of Charles IX. Before that time they began the day next after Easter, about the 25th of March. In England, also, till of late, we had two beginnings of the year, one in January, and the other on March 25; but by act of parliament in 1752, the first day in January was appointed to be the beginning of the year for all purposes.

Most of the eastern nations distinguish the year by the reigns of their princes. The Greeks also had no better method, giving names to them from the magistrates who presided in them, as in Athens from the Archons. The Romans also named the year by the consuls; and it was a long time before any people thought of giving names to the years from any particular æra or remarkable event. But at length the Greeks reckoned from the institution of the Olympic games, and the Romans from the building of Rome. They did not, however, begin to make these computations till a number of years had elapsed since those events could not be computed with exactness, and therefore they have greatly antedated them.

About A. D. 360, the Christians began to reckon the years from the birth of Christ, but not time enough to enable the chronologers of that age to fix the true time of that event.

The Greeks distributed their years into systems of four, calling them Olympiads, from the return of the Olympic games every four years. And the Romans sometimes reckoned by *lustra*, or periods of five years.

The greatest difficulty in chronology has been, to accommodate the two methods of computing time by the

course of the moon and that of the sun, to each other; the nearest division of the year by months being twelve, and yet twelve lunar months falling eleven days short of a complete year. This gave birth to many cycles in use among the ancients, the principal of which are as follows:

It appears from the relation which Herodotus has given of the interview between Solon and Crœsus, that, in the time of Solon, and probably that of Herodotus also, it was the custom with the Greeks to add, or, as it is termed, to *intercalate*, a month every other year; but as this was evidently too much, they probably rectified it, by omitting the intercalation whenever they observed, by comparing the seasons of the year with their annual festivals, that they ought to do it. If, for instance, the first fruits of any kind were to be carried in procession on any particular day of a month, they would see the necessity of intercalating a month, if, according to their usual reckoning, those fruits were not then ripe, or they would omit the intercalation if they were ready. And had no other view interposed, their reckoning could never have erred far from the truth. But it being sometimes the interest of the chief magistrates to lengthen or shorten a year, for the purpose of ambition, every other consideration was often sacrificed to it, and the greatest confusion was introduced into their computations. Finding themselves, therefore, under a necessity of having some certain rule of computation, they first adopted four years, in which they intercalated only one month. But this producing an error of fourteen days in the whole cycle, they invented the period of eight years, in which they intercalated three months; in which was an excess of only one day and fourteen hours, and therefore this cycle continued in use much longer than either of the preceding.

But the most perfect of these cycles was that which was called the Metonic, from Meton, an Athenian astronomer, who invented it. It consisted of nineteen years, in which seven months were intercalated. This brought the two methods to so near an agreement, that after the expiration of the period, not only do the new and full moons return on the same day of the year, but very nearly on the same hour of the day. This cycle was adopted by the Christians at the council of Nice, for the purpose of settling the time for keeping Easter, and other moveable feasts. This period, however, falling short of nineteen years almost an hour and a half, it has come to pass that the new and full moons in the heavens have anticipated the new and full moons in the calendar of the book of Common Prayer four days and a half. These last are called *calendar new moons*, to distinguish them from the true new moons in the heavens.

It has not been without difficulty and variety that the computation by years has been accommodated to that by days; since a year does not consist of any even number of days, but of 365 days, 5 hours, and 49 minutes nearly. It will appear from what has been observed, that so long as mankind computed chiefly by months, it was not of much consequence to determine with exactness the number of days in the year; and this method sufficiently answered every civil and religious purpose. But the Egyptians, and other nations addicted to astronomy, were not satisfied with the method of computing by lunar months, the days of which varied so very much from one another in different years. They therefore made the year the standard; and dividing that into days, made use of months only as a commodious intermediate division; and, without regard to the course of the moon, distributed the days of the year into twelve parts, as nearly equal as they conveniently could. By this means the same day of the month would fall on the same part of the sun's annual revolution, and therefore would more exactly correspond to the seasons of the year. The Mexicans divided their year into eighteen parts.

The Egyptians, as also the Chaldeans and Assyrians, reckoned at first 360 days to the year, but afterwards 365. The consequence of this was, that the beginning of their year would go back through all the season, though slowly; namely, at the rate of about six hours every year. Of this form too were the years which took their date from the reign of Nabonassar of Babylon, Yesdigerd of Persia, and the Seleucidæ of Syria.

It must be observed, however, that the people who reckoned their year from these epochas, namely, the Egyptians, Persians, and Jews, as also the Arabians, had a different and more fixed form of the year for astronomical purposes; but as no use was made of it in civil history, the account of it is omitted in this place.

The inconvenience attending the form of the year above-mentioned, was in a great measure remedied by the Romans in the time of Julius Cæsar, who added one day every fourth year, which (from the place of its insertion, viz. after the sixth of the calends of March) was called *bissextile*, or leap-year. This form of the year is still called the Julian year. But the true length of the year being not quite six hours more than the 365 days, this allowance was too much; and pope Gregory XIII. introduced another amendment, in the year 1582, by ordering that once in 133 years a day should be taken out of the calender, in the following manner, viz. from the year 1600 every hundreth year (which, according to the Julian form, is always bissextile or leap-year) was to be common; but every four-hundredth year was to continue bissextile, as in the Julian account.

The Mahometans make their year to consist of lunar months only, without endeavouring to adapt it to the course of the sun; so that with them the beginning of the year goes through all the seasons at the rate of about eleven days every year. But since the exact time of twelve moons, besides the 354 whole days, is about 8 hours and 48′, which make 11 days in 36 years, they are forced to add 11 days in 30 years, which they do by means of a cycle, invented by the Arabians, in which there are 19 years with 354 days only, and 11 intercalary of 355 days, and they are those in which the num- of hours and minutes more than the whole days in the year is found to be more than half a day, such as 2, 5, 7, 10, 13, 16, 18, 21, 24, 26, and 29, by which means they fill up all the inequalities that can happen.

It has been of some consequence to Christians to adjust the days of the week to the days of the month, and of the year, in order to get a rule for finding Sunday. Had there been no bissextile, it is evident that, since the year consists of 52 weeks and 1 day, all the varieties would have been comprised in seven years. But the bissextile returning every fourth year, the series of dominical letters succeeding each other is interrupted, and

does not return in order; but after four times 7 years, or 28 years, which is therefore commonly called the solar cycle, serve as a rule to find Sunday, and consequently all the days of the week of every month and year.

Besides the above-mentioned periods of years, called cycles, there are some other combinations or systems of years that are of use in chronology; as that called the *indiction*, which is a period of 15 years, at the end of which a certain tribute was paid by the provinces of the Roman empire, and by which the emperors ordered public acts to be dated.

But the most remarkable of all the periods in chronology, is that called the Julian period, invented by Joseph Scaliger; and called Julian, from the years of which it consists being Julian years. His object was to reduce to a certainty the different methods of computing time, and fixing the dates of events by different chronologers. For this purpose nothing was necessary but a series of years, some term of which was fixed (that, for instance, by which the present year should be denominated), comprehending the whole extent of time; since, if each chronologer would apply that common measure to his particular scheme, they would all perfectly understand one another. To accomplish this, he combined the three periods of the sun, the moon, and the indiction, together; that is, multiplying the numbers 28, 19, and 15, into one another, which produces 7980; after which period, and not before, all the three cycles will return in the same order every year, being distinguished by the same number of each. In order to fix the beginning of this period, he took the cycles as he then found them settled in the Latin church; and tracing them backwards through their several combinations, he found that the year in which they would all begin together was the year before the creation 714, according to Usher; and that the first year of the Christian æra would be 4714 of this period. There is a farther convenience in this period, viz. that if any year is divided by the number composing the cycles, viz. 28, 19, or 15, the quotient will show the number of the cycles that have elapsed since the commencement of it, and the remainder will give the year of the cycle, corresponding to the year given.

We cannot help observing that this boasted period seems to have been unnecessary for the chief purpose for which it was invented, viz. to serve as a common language for chronologers; and that now little use is made of it, notwithstanding all writers still speak of it in the same magnificent terms. The vulgar Christian æra answers the same purpose as effectually.

All that can be necessary for chronologers to speak the same language, and be perfectly understood by one another, and by all mankind, is to give every year the same name or designation; which is most conveniently done by expressing them in a series of numbers in arithmetical progression, any one term of which they shall agree to affix to the same year, a year in which any well known event happened. Let it, for example, be that in which the peace of Amiens was made, and let it be called 1801. If, besides this, it is only agreed in what part of the revolution of the sun, or in what month and day, the year begins, there can be no difficulty in giving a name to every other year preceding or following it, and thereby ascertaining the interval between all transactions. For all the events that took place the year before that peace, will be referred to the year 1800, and all in the year after it to 1802. This period having had a commencement since the date of history, is no inconvenience; for whenever we have gone back to number 1 of this period, the year preceding it may be called *one before its commencement*, the year preceding that *two* before it, &c. and thus proceeding *ad infinitum* both ways.

That Christ might not have been born in the first of that system of years to which it serves to give a name, is no inconvenience whatever; since, whatever differences of opinion there may be among chronologers about the time when Christ was born, they all agree in calling the present year, and consequently every other year, by the same name; and therefore they have the same idea of the interval between the present year and any other year in the system. The real time of Christ's birth can no more affect the proper use of this system than that of any other indifferent event; since, using the same system of dates, they may say Christ was born in the third, fourth, fifth, or sixth year before the Christian æra.

Whenever, therefore, chronologers ceased to date events from the Creation, which was very absurd (since they did not agree in fixing the intervals between the present year and the date of that event, and therefore gave all the years different names), they had no occasion to have recourse to any such period as the Julian; since another, capable of answering the same purposes, was already in common use, supplying them with a language which they all equally understood.

Æras or epochas are memorable events from which time is reckoned, and from which any subsequent year receives its denomination. The Greeks for a long time had no fixed æra; afterwards they reckoned by Olympiads, which were games celebrated in honour of Jupiter once in four years, and began in midsummer, 776 years before Christ. The Athenians gave names to their years from their archons. The Romans called their years from the names of the consuls who presided in them; and afterwards they dated events from the building of their city, supposing it to have been built 753 years before Christ.

Some histories are regulated by the æra of Nabonassar, who began his reign in the year 747 before Christ, of the Julian period 3867. It is supposed to have commenced on the 26th of February, in the afternoon.

The Jews before Christ reckoned by the year of the Seleucidæ, sometimes called the year of the Contracts; which began in the year 312 before Christ, of the Julian period 4402, some time in the spring.

The Christians, about 360 years after the birth of Christ, began to make use of that æra, which is now used in all Christian countries.

The Mahometans reckon their years from the flight of Mahommed from Mecca. This æra is called the Hegyra. It began in the year 622 after Christ, of the Julian period 5335, on the 16th of July.

The old Spanish æra is dated from the year 38 before Christ, about the time when they were subdued by the Romans. It was used till the year 1383, under John I. of Castile.

The Egyptians long reckoned from the battle of Ac-

tium, which happened in the year 31 before Christ, of the Julian period 4683, on the 3d of September.

Before the Christian æra was used, the Christians for some time made use of the Dioclesian æra, which took its rise from the persecution by Diocletian, in the year 284 after Christ.

The æra of Yerdigerd is dated from the last king of Persia; who was conquered by the Saracens under Abubecher, in the battle of Merga, in the year 632 after Christ, of the Julian period 5345, on the 16th of June.

With regard to all these methods of denominating time, care must be taken that the year be reckoned according to the method of computation followed by the people who use it. Thus, in reckoning from the Hegyra, a person would be led into a mistake who should make those years correspond to Julian years. He must deduct eleven days from every year which has elapsed since the commencement of it. Thus, though the first year of this æra corresponded to the year 622 after Christ, and began on the 16th of July, the year 326 of the Hegyra corresponded to the year 937 of Christ, and began November 8: and the year of the Hegyra 655 commenced on the 19th of January, 1257.

This compendium of chronology is sufficient for the purpose of reading history, but is by no means a complete account of the methods of computing time in every particular country which has been mentioned. To have done this, would have carried us beyond our present purpose, and too far into the customs of particular countries. For a fuller account, the reader may be referred to Dr. Blair, and other chronologers.

PROBLEMS IN CHRONOLOGY.

1. To find whether any given year be leap-year.

Rule.—Divide the given year by 4: if 0 remains, it is leap-year; but if 1, 2, 3, remains, it is so many years after.

Every fourth year is leap-year, so called from leaping or advancing a day more that year than any other; that year has then 366 days in it, and February 29.

2. To find the dominical letter before the year 1800.

Rule.—To the given year add its fourth part, omitting fractions; divide that sum by 7; the remainder taken from 7 leaves the index of the letter in the common year's reckoning.

1	2	3	4	5	6	7
A	B	C	D	E	F	G

But in leap-years this letter and its preceding one (in the retrograde order which these letters take) are the dominical letters.

The dominical letter is that letter of the alphabet which points out in the calendar the Sundays throughout the year; thence also called the Sunday letter. Of these letters there are consequently seven before mentioned, beginning with the first letter of the alphabet; and as in leap-year there is an intercalary day, there are then two; one serving January and February, and its following letter the remaining part of the year.

3. To know on what day in the week any proposed day of the month will fall.

Rule. First find the dominical letter, then the day of the week the first of the proposed month falls on, which is known by the two following lines:

At Dover Dwell George Brown, Esquire,
Good Christopher Finch, and David Frier:

where the first letter of each word answers to the letter belonging to the first day of the months in order, from January to December. If I would know on what day of the week the 24th of June will be this year (1806,) I find the dominical letter is E, and by the lines just read, E is the first of June, which is, of course, Sunday; the 22d also is Sunday, therefore the 24th will be a Tuesday.

4. To find the year of the solar, lunar or golden number, and indiction cycles.

Rule. To the given year add 9 for the solar, 1 for the lunar, 3 for the indiction: divide the sums in order by 28, 19, and 15, the remainder in each shows the years of its respective cycle.

The solar cycle, or the cycle of the sun, is a period of 28 years; in which time all the varieties of the dominical letters will have happened, and the 29th year the cycle begins again, when the same order of the letters will return as were 28 years before.

At the birth of Christ, nine years had passed in this cycle.

The lunar cycle, or cycle of the moon, or golden number, is a period of 19 years; containing all the variations of the days on which the new and full moons happen, after which time they fall on the same days they did 19 years before, and she begins again with the sun.

But when a centesimal or hundredth year falls in the cycle, the new and full moon, according to the new style, will fall a day later than otherwise. The birth of Christ happened in the second year of this cycle.

The Roman indiction is a cycle of 15 years, which first began the third year before Christ.

5. To find the epact till the year 1900.

Rule. Multiply the golden number for the given year by 11; divide that product by 30, and from the remainder take 11, leaves the epact. If the remainder is less than 11, add 19 to it, and the sum will be the epact.

6. To find the moon's age.

Rule. To the epact add the number and day of the month; their sum, if under 30, is the moon's age. But if that sum is above 30, the excess in month of 31 days, or the excess above 29 in a month of 30 days, shows the age or days since the last conjunction.

The moon's age taken from 30, leaves the day of the next new moon.

When the solar and lunar cycles begin together, the moon's age on the first of each month, or the monthly epacts, are called the numbers of the month, and are as follows, viz.

For	Jan.	Feb.	March.	April.	May.	June.
These	0.	2.	1.	2.	3.	4.
For	July.	Aug.	Sept.	Oct.	Nov.	Dec.
These	5.	6.	7.	8.	9.	10.

7. To find when Easter-day will happen.

Rule. Find on what day of March the new moon falls nearest to the 21st in common years, or nearest the 20th in leap-years; then the Sunday next after the full, or 15th day of that new moon, will be Easter day.

If the 15th day falls on a Sunday, the next Sunday is Easter-day.

Among the earliest writers on chronology, after the discovery of printing, was Paulus Constantinus Phrygio,

whose "Chronicon Regum Regnorumque omnium" was printed at Basil in 1534. A second was Bibliander's work, in 1558; and a third, Eggard's "Tabulæ Chronologicæ," printed at Rostock, 1577. Among the most valuable which are now in use upon the continent, are the tables of Du Fresnoy and Berger, both originally published in 1719. The title only of the latter, we believe, ("Synchronistische Universal Historie,") is known in England; but those of the former have been long received in credit; although they are now superseded not only by Dr. Blair's Tables, but by professor Playfair's System of Chronology. 1784.

The following, as the greater epochs in the chronology of history, have been selected from Dr. Blair. The history of the intervals may be easily supplied by the memory of a retentive reader.

[In order to render the work more interesting to his patrons, the American editor has introduced the most remarkable events contained in the history of America, and continued the table from 1805, to the present period. (*a*)

Before Christ.

4004 Creation of the world
3875 The murder of Abel
3874 The birth of Seth
3017 Enoch translated
2348 The deluge
2247 The tower of Babel built
2000 The birth of Abraham
1921 The covenant made with Abraham
1728 Joseph sold into Egypt
1689 The death of Jacob
1635 The death of Joseph, which concludes the book of Genesis
1574 The birth of Aaron
1571 The birth of Moses
1491 God's appearance to Moses in the burning bush
1451 The Israelites under Joshua pass the river Jordan
1285 Deborah defeats the Canaanites
1263 The Argonautic expedition undertaken
1236 The death of Gideon
1188 Jephthah's vow
1184 Troy taken
1117 Sampson betrayed to the Philistines
1104 The return of the Heraclidæ to Peloponnesus
1095 The Israelites ask for a king—Saul anointed
1070 Athens governed by archons
1048 Jerusalem taken by David
1044 The migration of the Ionic colonies from Greece
1023 Absalom's rebellion
1004 Solomon's dedication of the temple
926 The birth of Lycurgus
907 Homer supposed to have flourished
897 The death of Ahab
896 Elijah's translation
814 The kingdom of Macedon begins
800 Jonah prophesies
790 Amos
785 Hosea
758 Nahum
757 Isaiah, who prophesied above sixty years
754 Micah prophesies
753 The æra of the building of Rome

Before Christ.

750 The rape of the Sabines
731 Habakkuk prophesies
721 Samaria taken—The first eclipse of the moon upon record
710 Senacherib's army destroyed
696 Isaiah the prophet put to death
686 Archilochus the poet flourishes
677 The combat of the Horatii and Curiatii
658 Byzantium built
627 Jeremiah prophesies
628 Zephaniah
623 Draco establishes his laws at Athens
605 The beginning of the captivity
600 Sappho flourishes
593 Ezekiel prophesies
591 Institution of the Pythian games
587 Jerusalem taken by Nebuchadnezzar
560 Pisistratus usurped the tyranny of Athens
558 Daniel prophesies
539 Pythagoras flourishes
536 Cyrus gives an edict for the return of the Jews
528 Haggai prophesies
527 Zechariah
525 Cambyses conquers Egypt
520 Confucius flourishes
515 The temple of Jerusalem finished
509 The consular government begins at Rome
490 The battle of Marathon
480 The defeat of Salamis
458 Ezra flourishes
456 Nehemiah the prophet
451 Laws of the twelve tables compiled
445 Herodotus reads his history at Athens
431 Beginning of the Peloponnesian war
430 About this time the history of the Old Testament finishes
401 The retreat of the 10,000 Greeks under Xenophon. The thirty tyrants expelled from Athens by Thrasybulus.
398 The military catapultæ invented
390 Plato made his first voyage into Sicily
357 Dionysius the tyrant expelled Syracuse
343 The war between the Romans and Samnites
340 The Carthaginians defeated by Timoleon
336 Philip of Macedon killed by Pausanias
327 Alexander's expedition into India
323 The death of Alexander
322 Demosthenes put to death by Antipater
296 Athens taken by Demetrius Poliorcetes
286 Lysimachus takes possession of Macedon
284 The septuagint translation of the Old Testament thought to have been made
278 The Gauls under Brennus cut to pieces
264 The beginning of the first Punic war
260 The Carthaginians defeated at sea by the Romans
256 Regulus defeated by the Carthaginians
241 Agis, king of Sparta, put to death
235 The temple of Janus shut the first time after Numa
224 The colossus of Rhodes thrown down by an earthquake
218 The second Punic war begins—Annibal passes the Alps

Before Christ.

216 The battle of Cannæ
212 Syracuse taken by Marcellus
202 Annibal defeated at Zama
200 The first Macedonian war begins
190 The first Roman army enters Asia
187 Antiochus the Great defeated and killed
167 The first library erected at Rome
149 The third Punic war begins
146 Carthage destroyed by Publius Scipio
137 Ptolemy Physcon began a new restoration of learning at Alexandria
116 Cleopatra assumes the government of Egypt
107 Cicero born
101 Marius and Catullus defeat the Cimbri
100 The birth of Julius Cæsar
99 Lusitania conquered by the Romans
89 The Mithridatic war begins
81 Cicero made his first oration
66 Mithridates defeated by Pompey
65 The reign of the Seleucidæ ends in Syria
63 Cataline's conspiracy detected
55 Cæsar's first expedition against Britain
50 Cæsar besieges Pompey in Brundusium
48 The battle of Pharsalia
44 Cæsar killed in the senate-house
40 Jerusalem occupied by Antigonus
31 The battle of Actium: Marc Antony and Cleopatra defeated
25 The Egyptians adopt the Julian year
8 Augustus corrects the calendar
4 Our Saviour's birth: four years before the common æra.

CHRISTIAN ÆRA.

After Christ.

8 Our Saviour disputes with the Jewish doctors
14 Augustus dies at Nola
17 Twelve cities in Asia destroyed by an earthquake
26 St. John the Baptist enters on his ministry
27 John baptizes our Saviour
33 Our Saviour's crucifixion
36 St. Paul converted
37 Tiberius dies at Misenum
39 St. Matthew writes his gospel
43 Claudius's expedition into Britain
44 St. Mark wrote his gospel
51 Caractacus carried in chains to Rome
52 The council of the Apostles at Jerusalem
54 The death of Claudius
59 Nero puts his mother Agrippina to death
61 Boadicea, the British queen, defeats the Romans
62 St. Paul sent in bonds to Rome
64 The first persecution against the christians
66 The Jewish war begins
67 St. Peter and St. Paul put to death
70 Titus destroys Jerusalem
95 The second persecution against the christians
102 Pliny the Younger sends Trajan his celebrated account of the christians
107 The third persecution against the christians
118 The fourth persecution against the christians
130 Adrian rebuilds Jerusalem
135 Conclusion of the Jewish war, when the Jews were all banished Judea

After Christ.

146 The worship of Serapis introduced at Rome
202 The fifth persecution against the christians
235 The sixth persecution against the christians
250 The seventh persecution
252 A great pestilence in the Roman empire
257 The eighth persecution of the christians
269 Zenobia takes possession of Egypt
272 The ninth persecution against the christians
293 Carausius killed by Alectus
286 The Roman empire attacked by the northern nations. Carausius reigns in Britain.
303 The tenth persecution against the christians
312 Maxentius defeated by Constantine
319 Constantine begins to favour the christians
325 The first general council of Nice
340 The death of Constantine the Great
343 Persecution of the christians in Persia
364 The Roman empire divided into the eastern and western
388 The tyrant Maximus defeated
406 The Vandals, Alans, and Suevi, spread into France and Spain
410 Rome taken and plundered by Alaric
420 The kingdom of the French begins upon the lower Rhine
426 The Romans leave Britain
435 The Theodosian codex published
449 The Saxons arrive in Britain
452 The city of Venice takes its rise
455 Rome taken by Genseric
475 Hengist's massacre of the British nobles
476 The western empire finishes
493 The kingdom of Italy passes from the Heruli to the Ostro-Goths
496 Clovis baptized, and christianity embraced in France
510 Paris made the capital of the French dominions
511 Arthur defeatsthe Saxons in the battle of Badon-hill
516 The computing of time by the christian æra introduced by Dionysius
529 The code of Justinian published
533 The digest of Justinian published
536 Rome taken by Belisarius
551 The manufacture of silk introduced into Europe from India by some monks
558 A terrible plague all over Europe, Asia, and Africa, which continues near fifty years
580 Cosroes the Great defeated, and dies of grief
597 Augustin the monk arrives in England
606 The power of the popes begins
622 The Hegira of Mahomet begins
637 Jerusalem taken by the Saracens
640 Alexandria taken by the Saracens, and the great library there burnt
653 The Saracens take Rhodes, and cut to pieces the famous colossus
709 Ina, king of Wessex, publishes his laws
748 The computing of years from the birth of Christ began to be used in histories about this time
750 The Merovingian race ends in France
751 The second race of the French kings begins with Pepin, surnamed the little
762 Bagdad built by Almansor

After Christ.

774 Pavia taken by Charlemagne
778 The battle of Roncevaux
800 The emperors of the West, or of Germany, begin
822 The Saracens besiege Constantinople
810 A civil war among the Saracens
828 The heptarchy of England united under Egbert
838 The Picts defeated by the Scots
840 The death of Lewis the Debonnaire
843 The French peers make a new division of the French dominions
853 The Normans get possession of some cities in France
867 The Danes conquer Northumberland
872 Alfred defeated by the Danes
878 Alfred conceals himself in Arthelney
879 The kingdom of Arles begins
886 The university of Oxford said to have been founded
888 The dominions of Charles le Gros divided into five kingdoms
904 The Hungarians ravage Italy
912 The Normans establish themselves in France under Rollo
936 The Saracen empire divided by usurpation into seven kingdoms
964 The kingdom of Italy conquered by Otho
987 The third race of the French kings begins under Hugh Capet
996 Otho III. makes the empire of Germany elective
1013 The Danes, under Sueno, get possession of England
1035 The kingdoms of Castile and Arragon begin
1043 The Turks take possession of Persia
1065 Jerusalem taken by the Turks from the Saracens
1066 The conquest of England under William duke of Normandy
1080 The Domesday survey compiled
1096 The first crusade to the Holy Land
1110 Learning revived at the university of Cambridge
1118 The order of the knights templars instituted
1140 King Stephen defeated and taken prisoner in the battle of Lincoln
1146 The empress Matilda retires out of England
1147 The second crusade
1151 The canon law composed by Gratian
1154 The party names of Guelfs and Gibbelines begin
1162 The emperor Frederick destroys Milan
1172 Henry II. takes possession of Ireland
1177 Saladin repulsed before Jerusalem
1189 The kings of England and France go to the Holy Land
1192 Richard Cœur de Lion defeats Saladin at Ascalon
1204 Normandy conquered, and re-united to France
1215 Magna Charta signed by king John
1227 The Tartars under Gingis-kan over-run the Saracen empire
1233 The inquisition trusted to the Dominicans
1253 The famous astronomical tables are composed by Alfonso XI. king of Castile
1273 The empire of the present Austrian family begins
1279 The mortmain-act passed in England
1283 Wales conquered by Edward the First

After Christ.

1293 The regular succession of the English parliaments begins
1307 The beginning of the Swiss cantons
1310 The knights of St. John take Rhodes
1312 The knights templars condemned
1346 The battle of Cressy
1349 The order of the garter instituted
1352 The Turks enter Europe
1356 The battle of Poictiers
1381 Wat Tyler's insurrection
1388 The battle of Otterburn
1414 The council of Constance
1440 The art of printing discovered
1455 The battle of St. Albans
1471 The battle of Tewksbury
1478 Lorenzo de Medici expelled Florence
1485 The battle of Bosworth
1492 Columbus discovers America
1497 The Portuguese first sail to the East Indies
1498 North America discovered by Cabot
1508 The league of Cambray formed
1517 The Reformation begun by Luther
1522 Rhodes taken by the Turks
1527 Rome taken by Charles V.
1534 The Reformation takes place in England
1545 The council of Trent begins
1571 The victory of Lepanto obtained
1572 The massacre of Paris
1582 Pope Gregory introduces the new style
1587 Mary queen of Scots beheaded
1588 The destruction of the Spanish armada
1596 Cadiz taken by the English
1604 Ostend taken by the Spaniards
1608 The invention of the telescope
1609 New York discovered by Henry Hudson
1614 Napier invents the logarithms
1616 Tobacco first cultivated in Virginia
1618 The synod of Dort begins
1619 Harvey discovers the circulation of the blood
1621 The civil war with the Huguenots in France
1623 The first literary production, by an English colonist, in America, being a translation of Ovid's Metamorphoies, by George Sandays, treasurer of the Virginia company
1628 Salem, Massachusetts, founded
1629 Nine members imprisoned for their speeches in the house of commons
1634 Maryland settled by Lord Baltimore
1635 Providence Plantation begun by Roger Williams
1639 First Printing Press in North America established at Cambridge
1640 The Scots army enters England
1642 King Charles demands the five members
1645 The battle of Naseby
1649 King Charles beheaded
1652 The first war between the English and Dutch begins
1660 The restoration of Charles II.
1661 The Testament translated into the Indian language and printed—The Bible was completed about eight years afterwards
1662 The Royal Society established

After Christ.

1680 The great comet observed
1681 Grant of Pennsylvania to Wm. Penn
1682 Wm. Penn arrives in America, and lands at New Castle—City of Philadelphia laid out
1683 Lord Russel beheaded
1687 The first Printing Press established in Philadelphia
1688 The Revolution in England
1692 The sea-fight of La Hogue
1693 The government of Pennsylvania assumed by the king and queen of England
1694 The government of Pennsylvania restored to Wm. Penn
1704 The first news-paper published in America, called the Boston News Letter—Gibraltar taken by admiral Rook
1706 The battle of Ramillies
1709 The battle of Pultowa
1718 William Penn, the founder of Pennsylvania, died, aged 74 years
1719 The first news-paper printed in Philadelphia, called the American Weekly Mercury
1720 The South Sea scheme begins
1727 The siege of Gibraltar by the Spaniards
1750 The interest on the public funds reduced to three per cent.
1752 The new style introduced into Great Britain—Franklin's electrical discovery
1753 The University of Pennsylvania founded
1766 The American stamp-act repealed
1768 Circular letters against the duties lately imposed, sent by Massachusetts to the other colonies—The circular letter of Massachusetts gives great offence to the English ministers. The house of representatives of that colony are required to rescind the resolution which authorised it—She refuses to rescind her resolutions—August 4, the governor of Massachusetts dissolves the general assembly—Sept. 22, convention meet at Boston—28, two British regiments arrive at Boston from Halifax—Great offence is given to the inhabitants of the town, by their being quartered in the state house, and in other public buildings. The council also refuses to provide barracks for them
1769 The Massachusetts legislature refuses to make provision for quartering the troops. On this the governor prorogues it to the 10th of January—The American Philosophical Society instituted—its meetings to be held in Philadelphia—August 15, Bonaparte born at Ajaccio in Corsica
1770 March 5, massacre at Boston—April 22, the duties repealed, with the exception of three pence per pound on tea. This occasions an agreement not to make use of tea until the duty thereon should be repealed
1772 The Gasper armed schooner burnt by the inhabitants of Providence, Rhode Island—The revolution in Denmark
1773 The order of the Jesuits suppressed
1774 September 5, the first continental congress meet at Philadelphia

After Christ.

1775 The American war commences with Great Britain—April 19, battle of Lexington, between a detachment of British and Americans. The object of the British was to destroy the military stores collected at Concord, in which they succeeded. On their return to Boston, they were very much harrassed by the Americans. The loss of the British was 65 killed, 180 wounded, and 28 prisoners. The loss of the Provincials, or Americans, was 50 killed, 34 wounded, and 4 missing—An army of upwards of 20,000 Americans assembled near Boston—May 15, congress establishes a paper currency—June 14, general Washington appointed commander in chief of the forces of the confederated colonies by the general congress—17, Battle of Breeds, or Bunker's Hill, in which the Americans, after having twice repulsed the attacks of the British, are forced to retreat over the Charlestown neck, for want of powder. The loss of the British was 226 killed and 828 wounded. The Americans had 139 killed, and 314 wounded and missing
1776 May 15, congress abolishes the authority of Great Britain over the colonies—July 4, the Independence of the colonies is declared by congress, and first styled the United States by a resolution of congress—December 28, congress resolves to send commissioners to the courts of Vienna, Madrid, Prussia and Tuscany
1777 September 11, the battle of Brandywine—27, the British general Howe takes possession of Philadelphia—October 17, British general Burgoyne surrenders his army, upwards of 5000 men, prisoners to general Gates
1778 February 6, treaty of commerce and alliance concluded between France and the United States—June 18, Philadelphia evacuated by the British
1779 The siege of Gibraltar begun
1780 The riots in London
1781 October 19, Lord Cornwallis surrenders his army to the Americans and French—the prisoners amounted to 7073 men
1782 March 4, Resolution of the House of Commons against carrying on the war in America—November 30, provisional articles of peace agreed on—The Bank of North America established—The sea-fight under Rodney
1783 The preliminaries of a general peace signed. America declared Independent—The Independence of the United States acknowledged by the powers of Europe, and treaties concluded with them in the months of February, March, April and July—September 23, the definitive treaty of peace signed between Great Britain and the United States
1786 September 14, the first meeting of the commissioners in convention, at Annapolis, for the purpose of forming a federal constitution
1787 September 17, the federal constitution formed by the convention assembled at Philadelphia
1789 The revolution in France begins
1791 March 3, congress establishes a mint at Philadelphia—Washington City founded

After Christ.

1793 Above 4000 people die this year of the yellow fever in Philadelphia—Louis XVI. beheaded

1794 An insurrection takes place in the western part of Pennsylvania on account of duties being laid on spirituous liquors distilled in the country—November 19, Treaty of commerce between the United States and Great Britain signed at London

1796 Bonaparte appointed to the command of the army of Italy

1797 May 16, the French take possession of Verona

1798 May 20, Bonaparte sails for Egypt—About 3000 people in Philadelphia and 1000 in New York die of the Yellow Fever this year—The battle of the Nile

1799 Bonaparte made first consul of France—February 10, the American commodore Truxton, commanding the Constellation, takes the French frigate Insurgent—March 26, a treaty of peace concluded between the United States and Tunis—August 23, Bonaparte sails from Egypt for France—November 9, Bonaparte dissolves the conventional government

1800 Seat of government of the United States removed to Washington

1802 Definitive treaty between England and France—August 20, Swiss form of government changed by the interference of the French

1803 May 18, England declares war against France—April 30, Louisiana purchased of France by the United States for 15,000,000 dollars

1804 The attack on Tripoli by the Americans under the command of commodore Preble—May 18, Bonaparte made emperor—November 19, Bonaparte crowned by the Pope

1805 The victory off Trafalgar—April 11, treaty of Petersburg, between England, Russia, Austria and Sweden—May 26, Bonaparte declared king of Italy—December 9, Battle of Austerlitz

1806 September 24, Bonaparte marches against Prussia—May, a great part of the French coast declared to be in a state of blockade by the English government—November, the Berlin decree of the emperor of France, declaring the British islands in a state of blockade

1807 December 17, the Milan decrees of the emperor of France—22, a general embargo law passed by congress

1808 July 7, Bonaparte declared king of Spain

1809 April 6, war declared by Austria—Embargo law repealed

1810 By the census taken this year the inhabitants of the United States amounted to 7,239,903

1812 June 18, war declared against Great Britain by the United States—23, British orders in council revoked—August 13, the British sloop of war Alert of 20 guns taken by the U. S. frigate Essex—September 7, battle of Moskwa, or Borodina—14, French enter Moscow—October 22, evacuate it again

1813 May 16, Messrs. Gallatin and Bayard, commissioners to negociate with Great Britain, under the mediation of the emperor of Russia, sailed from New Castle, Delaware—June 4, armistice agreed on—September 28, Bonaparte evacuated Dresden—October 18, battle of Leipsic—December 1, declaration of the allies at Frankfort

1814 February 26, the Hon. Messrs. Clay and Russel, commissioners to treat with Great Britain, take their departure at New York in the corvette John Adams, to join the American commissioners previously sent to Gottenburgh—March 31, Allies enter Paris—April 11, Bonaparte abdicates the throne—May 8, arrives at Elba—December 24, treaty of peace between the United States and Great Britain signed at Ghent, and ratified at Washington February 17, 1815

1815 February 26, Bonaparte left Elba—March 20, enters Paris without bloodshed, and re-assends the French throne—June 18, battle of Waterloo, in which the French army was completely defeated—July 4, Bonaparte abdicates unconditionally the throne of France, and surrenders himself to the British government—Aug. 5th, sailed from Plymouth, England, for St. Helena, to which he was condemned by the British Board of Admiralty

CHRONOMETER, in general, denotes any instrument, or machine, used in measuring time. See CLOCK-WORK.

Several machines have been invented for measuring time, under the name of chronometers, upon principles very different from those on which clocks and watches are constructed. The lamp chronometer consists of a chamber-lamp, which is a cylindrical vessel about three inches high, and one inch diameter, placed in a stand. The inside of this vessel must be every where exactly of the same diameter. To the stand is fixed a handle which supports a frame, about twelve inches high, and four wide. This frame is to be covered with oiled paper, and divided into twelve equal parts by horizontal lines; at the end of which are written the numbers for the hours, from 1 to 12, and between the horizontal lines are diagonals that are divided into halves, quarters, &c. On the handle, and close to the glass, is fixed a style or gnomon. Now as the distance of the style from the flame of the lamp is only half an inch, if the distance of the frame from the style is only six inches, then, while the float that contains the light descends by the decrease of the oil one inch, the shadow of the style on the frame will ascend twelve inches, that is, its whole length, and show by its progression the regular increase of the hours with their several divisions. It is absolutely necessary, however, that the oil used in this lamp should be always of the same sort, and quite pure, and that the wick also be constantly of the same size and substance; as it is on these circumstances, and the uniform figure of the vessel, that the regular progress of the shadow depends.

CHROSTASIMA, in natural history, a genus of pellucid gems, comprehending all those which appear of one simple and permanent colour in all lights: such are the diamond, carbuncle, ruby, garnet, amethyst, sapphire, beryl, emerald, and the topaz.

CHRYSALIS, or AURELIA, in natural history, a state of rest and seeming insensibility, which butterflies,

moths, and several other kinds of insects, must pass through before they arrive at their winged or most perfect state. In this state, no creatures afford so beautiful a variety as the butterfly kinds, and they all pass through this middle state without one exception. The figure of the aurelia or chrysalis generally approaches to that of a cone; or at least the hinder part of it is in this shape; and the creature, while in this state, seems to have neither legs nor wings, nor to have any power of walking. It seems indeed to have hardly so much as life. It takes no nourishment in this state, nor has it any organs for taking any: and indeed its posterior part is all that seems animated, this having a power of giving itself some motions. The external covering of the chrysalis is membranaceous, and considerably large, and is usually smooth and glossy: but some of them have a few hairs: some are also as hairy as the catterpillars from which they are produced; and others are rough or shagreened all over. In all of these there may be distinguished two sides; the one of which is the back, the other the belly of the animal. On the anterior part of the latter, there may always be distinguished certain little elevations running in ridges, and resembling the fillets wound about mummies: the part whence these have their origin is esteemed the head of the animal. The other side, or back, is smooth, and of a rounded figure in most of the chrysalises; but some have ridges on the anterior part, and sides of this part: and these usually terminate in a point, and make an angular appearance on the chrysalis.

From this difference is drawn the first general distinction of these bodies. They are by this divided into two classes; the round and the angular kinds. There are also several subordinate distinctions of these kinds; but, in general, they are less different from one another than the catterpillars whence they are produced. The head of those of the first class usually terminates itself by two angular parts, which stand separate one from another, and resemble a pair of horns. On the back, eminences and marks are discovered, which imagination may form into eyes, nose, chin, and other parts of the human face.

There are a great variety and a great deal of beauty in the figures and arrangement of the eminences and spots on the other parts of the body of the chrysalises of different kinds. It is a general observation, that those chrysalises which are terminated by a single horn, afford day-butterflies of the kind of those which have buttoned antennæ, and the wings of which, in a state of rest, cover the under part of their body, and which use all their six legs in walking, those of many other kinds using only four of them. Those chrysalises which are terminated by two angular bodies, and which are covered with a great number of spines, and have the figure of a human face on their back in the greatest perfection, afford butterflies of the day-kind; and of that class the characters of which are, their walking on four legs, and using the other two, that is, the anterior part, in the manner of arms or hands. The chrysalises which have two angular bodies on their heads, but shorter than those of the preceding, and whose back shows but a faint sketch of the human face, and which have fewer spines, and those less sharp, always turn to that sort of butterfly the upper wings of which are divided into segments, one of which is so long as to represent a tail, and whose under wings are folded over the upper part of the back. A careful observation will establish many more rules of this kind, which are not so perfect as to be free from all exceptions; yet are of great use, as they teach us in general what sort of fly we are to expect from the chrysalis, of which we know not the catterpillar, and therefore can only judge from appearances. These are the principal differences of the angular chrysalises; the round ones also have their different marks not less regular than those.

The greater number of the round chrysalises have the hinder part of their body of the figure of a cone; but the upper end, which ought to be its circular plane base, is usually bent and rounded into a sort of knee; this is usually called the head of the chrysalis; but there are also some of this knid, the head of which is terminated by a nearly plane surface: some of the creeping ten-legged caterpillars give chrysalises of this kind, which have each of them two eminences that seem to bring them towards the angular kind.

Among the angular chrysalises there are some whose colours seem as worthy our observation as the shapes of the others. Many of them appear superbly clothed in gold. These elegant species have obtained the name of chrysalis and aurelia, which are derived from Greek and Latin words, signifying gold; and from these all other bodies of the same kind have been called by the same names, though less, or not at all, entitled to them. Some are all over of an elegant green, as is the chrysalis of the fennel caterpillar; others of an elegant yellow; and some of a bright greenish tinge, variegated with spots of a shining black; we have a very beautiful instance of this kind in the chrysalis of the cabbage-caterpillar. The general colour of the chrysalis of the common butterflies, however, is brown.

The several species of insects, as a fly, spider, and an ant, do not differ more evidently from one another in regard to appearance, than do a caterpillar, its chrysalis, and a butterfly produced from it; yet it is certain, that these are all the product of the same individual egg; and nothing is more certain, than that the creature which was for a while a caterpillar, is, after a certain time, a chrysalis, and then a butterfly. These great changes produced in so sudden a manner, seem like the metamorphoses recorded in the fables of the ancients; and indeed it is not improbable that those fables first took their origin from such changes.

The parts being distinguishable in the chrysalis, we easily find the difference of the species of the fly that is to proceed from it. The naked eye shows whether it is one of those that have, or those that have not, a trunk; and the assistance of a microscope shows the antennæ so distinctly, that we are able to discern whether it belongs to the day or night class; and often to what genus, if not the very species: nay, in the plumose horned kinds, we may see, by the antennæ, whether a male or female phalæna is to be produced from the chrysalis; the horns of the female being in this state evidently narrower, and appearing less elevated above the common surface of the body, than those of the male. All these parts of the chrysalis, however, though seen very distinctly, are laid close to one another, and seem to form only one mass; each of them is covered with its own peculiar membrane in this state, and all are surrounded together by a common one;

and it is only through these that we see them; or rather we see on these the figures of all the parts moulded within, and therefore it requires attention to distinguish them. The chrysalis is soft when first produced, and is wetted on the front with a viscous liquor; its skin, though very tender at first, dries and hardens by degrees: but this vicious liquor, which surrounds the wings, legs, &c. hardens almost immediately; and in consequence fastens all those limbs, &c. into a mass, which were before loose from one another: this liquor, as it hardens, loses its transparency, and becomes brown; so that it is only while it is yet moist that these parts are to be seen distinct.

It is evident from the whole, that the chrysalis is no other than a butterfly, the parts of which are hidden under certain membranes which fasten them together; and, when the limbs are arrived at their due strength, they become able to break through these membranes, and expand and arrange themselves in their proper order. The first metamorphosis, therefore, differs in nothing from the second, except that the butterfly comes from the body of the caterpillar in a weak state, with limbs unable to perform their offices, whereas it comes from the chrysalis perfect.

Mr. Reaumur, in his History of Insects, vol. 1. has given many curious particulars on the structure and use of the several coverings that attend the varieties of the caterpillar kind in this state. These creatures in general remain wholly immoveable, and seem to have no business in it but a patient attendance on the time when they are to become butterflies; and this is a change that can happen to them, only as their parts, before extremely soft and weak, are capable of hardening and becoming firm by degrees, by the transpiration of that abundant humidity which before kept them soft; and this is proved by an experiment of Mr. Reaumur, who, inclosing some chrysalises in a glass tube, found, after some time, a small quantity of water at the bottom of it; which could have come there no other way, but from the body of the inclosed animal. This transpiration depends greatly on the temperature of the air; it is increased by heat, and diminished by cold; but it has also its peculiarities in regard to the several species of butterfly to which the chrysalis belongs.

According to these observations, the time of the duration of the animal in the chrysalis state must be, in different species, very different; and there is indeed this wide difference in the extremes, that some species remain only eight days in this state, and others eight months.

CHRYSIS, or gold-fly, a genus of insects belonging to the hymenoptera order. The mouth is armed with jaws, but has no proboscis; the antennæ are filiform, bent, and consists of 12 articulations. The abdomen is arched, with a scale on each side; the anus is dentated, and armed with a sting; the wings lie plain, and the body appears as if gilt. There are seven species, of which the lucidula is one: it is beautified with the most splendid colours. The fore part of the head is green and gold, and the hinder of a bright azure. The thorax is azure and green: the abdomen is green and gold before, and of a coppery red behind. This species lives in holes of walls. The larvæ, which resemble those of the wasp, likewise inhabit the holes of decayed walls. See Plate XXXIII. Nat. Hist. fig. 120.

CHRYSITRIX, in botany: a genus of the diœcia order, in the polygamia class of plants. In the hermaphrodite, the glume is two-valved, the corollæ from chaff numerous and bristly; many stamina, one within each chaff; one pistillum. The male is the hermaphrodite: it has no pistillum. There is one species, a native of the Cape.

CHRYSOBALANUS, COCOA PLUM: a genus of the monogynia order, in the icosandria class of plants; and in the natural method ranking under the 36th order, pomaceæ. The calyx is quinquefid, the petals five; plum kernel five-furrowed and five-valved. There is only one species, the chrysobalanus icaco, a native of the Bahama islands and many other parts of America, but commonly grows near the sea. It rises with a shrubby stalk eight or nine feet high. The flowers are white, and are succeeded by plums like damsons; some blue, some red, and others yellow. The stone is shaped like a pear, and has five longitudinal furrows. The plums have a sweet luscious taste; and are brought to the tables of the inhabitants by whom they are much esteemed.

CHRYSOCOMA, GOLDY-LOCKS: a genus of the polygamia æqualis order, in the syngenesia class of plants; and in the natural method ranking under the 49th order, compositæ. The receptacle is naked; the pappus simple; the calyx hemispherical and imbricated; the style hardly longer than the florets. There are thirteen species, the most remarkable of which are the linosyris and the cernua. These are herbaceous flowering perennials, growing from one to two feet high, ornamented with narrow leaves, and compound floscular flowers of a yellow colour.

CHRYSOGONUM, a genus of the polygamia necessaria order, in the syngenesia class of plants; and in the natural method ranking under the 49th order, compositæ. The receptacle is paleaceous; the pappus monophyllous, and tridented: the calyx pentaphyllous; the seeds wrapped up each in a tetraphyllous calyculus, or little cup. There is one species, a native of Virginia.

CHRYSOLITE, in natural history, a gem which the ancients knew under the name of the topaz; and the true chrysolite of the ancients, which had its name from its fine gold-yellow colour, is now universally called topaz by modern jewellers.

The chrysolite is found in angular fragments, in grains, and crystallized. The primitive form of its crystals is a right angled parallelopid, whose length, breadth, and thickness, are as 5, $\sqrt{8}$, $\sqrt{5}$. The edges of the prism are usually truncated. The texture is foliated. Its fracture is conchoidal: it causes double refractions, and its specific gravity is from 3.265 to 3.45. Colour green. It is infusible at 150 degrees, but loses its transparency, and becomes a blackish grey. With borax it melts without effervescence into a transparent glass of a green colour. There are two varieties.

1. Common chrysolite, found in Ceylon, South America, and in Bohemia, amidst sandy gravel. Colour yellowish green, sometimes verging to olive-green, sometimes to yellow.

2. Olive chrysolite, found commonly in basalt; sometimes in small grains, sometimes in pretty large pieces.

It has not been observed in crystals: colour olive-green. The first variety is, according to the analysis of Klaproth, composed of

41.5 magnesia
38.5 silica
19.0 oxyde of iron.

99.0

The second is composed of

37.58 magnesia
50.00 silica
11.75 oxyde of iron
.21 lime

99.54

CHRYSOMELA, in zoology, a genus of insects with bracelet-like antennæ, thickest towards the extremities; the body of an oval form, and the thorax rounded. Of this genus, which belongs to the order of coleoptera, there are 122 different species, denominated from the trees on which they feed, as the chrysomela of tansy, beech, alder, willow, &c. some being of one colour, some of another, with a tinge of gold-colour diffused through it.

CHRYSOPHYLLUM, the BULLY TREE: a genus of the monogynia order, in the pentandria class of plants; and in the natural method ranking under the 43d order, viz. dumosæ. The corolla is campanulated, decemfid, with the segments alternately a little patent. The fruit is a ten-seeded berry. There are six species, natives of the West Indies. The most remarkable are:

1. The Chrysophyllum cainito, rises thirty or forty feet high. The flowers come out at the extremities of the branches, disposed in oblong bunches, which are succeeded by fruit of the size of a golden pippin, very rough to the palate, and astringent; but when kept some time mellow, as is practised here with medlars, they have an agreeable flavour.

2. Chrysophyllum glabrum, never rises to the height of the cainito, nor do the trunks grow to half the size. The flowers come out, clusters from the side of the branches, and are succeeded by oval smooth fruit, about the size of a bergamot pear. It contains a white clammy juice when fresh; but after being kept a few days, it becomes sweet, soft, and delicious. Inclosed are four or five black seeds, of the size of those of a pompkin. Both species are often preserved in large stoves.

CHRYSOPRASE. This mineral, which is found in several parts of Germany, is always amorphous. Its fracture is either even or inclined to the splintery, with very little lustre; its colour green; specific gravity 2.479. In a heat of 130 degrees Wedgewood, it whitens and becomes opaque. It is found by Klaproth to be composed of

96.16 silica
1.00 oxide of nickel
0.83 lime
0.08 alumine
0.08 oxide of iron.

98.15

CHRYSOSPLENIUM, a genus of the digynia order, in the decandria class of plants; and in the natural method ranking under the 12th order, succulentæ. The calyx is quadrifid or quinquefid, and coloured; no corolla; the capsule birostrated, unilocular, and polyspermous. Its English name is golden saxifrage. There are two species, common in all the northern parts of Europe.

CHUPMESSAHITES, a sect of Mahometans, who believed that Jesus Christ was God, and the redeemer of the world.

CHURCH, the place which christians consecrate to the worship of God. By the common law and general custom of the realm, it was lawful for earls, barons, and others of the laity, to build churches; but they could not erect a spiritual body-politic to continue in succession, and capable of endowment, without the king's licence; and before the law shall take knowledge of them as such, they must also have the bishop's leave and consent to be consecrated or dedicated by him. 3 Inst. 203.

CHURCHWARDENS, the guardians or keepers of the church, are persons annually chosen in Easter week, by the joint consent of the minister and parishioners, or according to the custom of the respective places; to look after the church and church-yard, and things thereunto belonging. They are entrusted with the care and management of the goods and personal property of the church, which they are to order for the best advantage of the parishioners; but they have no interest in, or power over, the freehold of the church itself, or of any land or other real property belonging to it: these are the property of the parson or vicar, who alone is interested in their loss or preservation. The churchwardens therefore may purchase goods and other articles for the use of the parish; they may likewise, with the assent of the parishioners, sell, or otherwise dispose of, the goods of the church, but without such consent they are not authorized to alienate any of the property under their care. 4 Viner Abr. 526.

All peers of the realm, clergymen, counsellors, attorneys, clerks in court, physicians, surgeons, and apothecaries, are exempt from serving the office of churchwardens; as is every dissenting teacher or preacher, in holy orders, or pretended holy orders.

By 2 Geo. III. c. 20. no serjeant, corporal, drummer, or private man, personally serving in the militia, during the time of such service, shall be liable to serve as churchwarden.

By the 10 and 11 Wm. c. 23. s. 2. persons who have prosecuted a felon to conviction, and the first assignee of the certificate thereof, are exempted.

No person living out of the parish may be chosen churchwarden. Gibs. 215.

CHYLE, in the animal economy, a milky fluid, secreted from the aliments by means of digestion. See PHYSIOLOGY.

CICATRIX, in surgery, a little seam or elevation of callous flesh rising on the skin, and remaining there after the healing of a wound or ulcer. It is commonly called a scar. See SURGERY.

CICADA, the FROG-HOPPER, or flea-locust, a genus of insects belonging to the order of hemiptera. See Plate XXXIII. Nat. Hist. figs. 121, 122. 123. The beak is inflected; the antennæ are setaceous: the four wings are membranaceous and deflected: and the feet in most of the species, are of the jumping kind. The species are fifty-one. The larvæ of several of this genus evacuate great quantities of a frothy matter upon the branches and leaves of plants, in the midst of which they constantly reside, probably

for shelter against the search of other animals, to which they would become a prey. Nature has afforded this kind of defence to insects whose naked and soft bodies might otherwise very easily be injured; perhaps also the moisture of this foam may serve to screen it from the sultry beams of the sun. On removing the foam, you discover the larva concealed underneath; but it does not long remain uncovered. It soon emits fresh foam, that hides it from the eye of observation. It is in the midst of this foamy substance that the larva goes through its metamorphosis into a chrysalis and perfect insect. Other larvæ, whose bodies are not so soft, run over plants without any manner of defence; and escape from insects that might hurt them, by the nimbleness of their running, but especially of their leaping.

The chrysalids, and all the larvæ that produce them, differ little from each other, only that the former have the rudiments of wings, a kind of knob at the place where the wings will afterwards be in the perfect insect. In other respects, the chrysalids walk, leap, and run, over plants and trees; as do the larva and the frog-hopper, which they are to produce. At length they throw off their teguments of chrysalids, slip their last slough, and then the insect appears in its utmost state of perfection. The male alone is then endowed with the faculty of singing, which it exercises not with its throat, but with an organ situated under the abdomen. Behind the legs of the male are observed two valvulæ, which, raised up, discover several cavities separated by various membranes. The middle contains a scaly triangle. Two vigorous muscles give motion to another membrane, which alternately becomes concave and convex. The air, agitated by this membrane, is modified within the other cavities; and by the help of this sonorous instrument, he amorously solicits his female. By pulling the muscles of a frog-hopper lately dead, it may be made to sing. This insect begins its song early in the morning, and continues it during the heat of the noontide sun. Its lively and animated music is, to the country people, a presage of a fine summer, a plentiful harvest, and the sure return of spring. The cicadæ have a head almost triangular, an oblong body, their wings fastigiated or in form of a roof, and six legs with which they walk and leap pretty briskly. In the females, at the extremity of the abdomen, are seen two large lamina, between which is enclosed, as in a sheath, a spine, or lamina, somewhat serrated, which serves them for the purpose of depositing their eggs, and probably to sink them into the substance of those plants which the young larvæ are to feed upon.

CICCA, a genus of the tetrandria order, in the monœcia class of plants. The male calyx is tetraphyllous; there is no corolla; the female calyx triphyllous; no corolla; four styles; the capsule quadricocceus, or four-berried. There is one species, a shrub of the East Indies.

CICER, the *chick-pea*, a genus of the decandria order, in the diadelphia class of plants, and in the natural method ranking under the 32d order, papilionaceæ. The calyx is quinquepartite, as long as the corolla, with its four uppermost segments incumbent on the vexillum; the legumen is rhomboidal, turgid, and dispermous. There is but one species, which produces peas shaped like the common ones, but much smaller. They are cultivated in Spain, where they are natives, being one of the ingredients in their olios, as also in France; but are rarely known in Britain.

CICHORIUM, *succory*, a genus of the polygamia æqualis order, in the syngenesia class of plants; and in the natural method ranking under the 49th order, compositæ. The receptacle is a little paleaceous; the calyx calyculated; the pappus almost quinquedentated; and indistinctly hairy. There are three species, viz.

1. Cichorium endivia, or common endive, with broad crenated leaves, differs from the wild sort (No. 2.) in its duration, being only annual, whereas the wild sort is perennial. This species may be considered both as an annual and biennial plant. If sown early in the spring, or even any time before the beginning of June, the plants very commonly fly up to seed the same summer, and perish in autumn. If sown in June and July they acquire perfection in autumn, continue till the next spring, then shoot up stalks for flower and seed, and soon after perish. The inner leaves are the useful parts. These when blanched white to render them crisp and tender, and reduce them from their natural strong taste to an agreeable bitter one, are then fit for use. They are valued chiefly as ingredients in autumn and winter salads, and for some culinary uses.

2. Cichorium intybus, wild succory, grows naturally by the sides of roads, and in shady lanes. It sends out long leaves from the roots, from between which the stalks arise, growing to the height of three or four feet, and branching out into smaller ones. The flowers come out from the sides of the stalks, and are of a fine blue colour. They are succeeded by oblong seeds covered, inclosed in a down. The roots and leaves are articles of the materia medica. The former have a moderately bitter taste, with some degree of roughness; the leaves are somewhat less bitter; and the darker-coloured and more deeply jagged they are, the bitterer is their taste. Wild succory is an useful detergent, aperient, and attenuating medicine, acting without much irritation, tending rather to cool than to heat the body; and, at the same time, corroborating the tone of the intestines. All the parts of the plant, when wounded, yield a milky saponaceous juice. This, when taken in large quantities, so as to keep up a gentle diarrhœa, and continued for some weeks, has been found to produce excellent effects in scorbutic and other chronical disorders.

3. Cichorium spinosum, with a prickly forked stalk, grows naturally on the sea-coast in Sicily, and the islands of the Archipelago. The flowers are of a pale blue colour, and are succeeded by seeds shaped like those of the common sorts.

CICINDELA, the *sparkler*, in zoology, a genus of insects belonging to the order of coleoptera. The antennæ are setaceous; the jaws are prominent, and furnished with teeth; the eyes are a little prominent; and the breast is roundish and marginated. There are 14 species. The campestris, (See Plate XXXIII. Nat. Hist. fig. 124), or field sparkler, is one of the most beautiful of the genus. The upper part of its body is of a fine green colour, rough, and rather bluish. The under side, as also the legs and antennæ, are of a shot colour, gold and red, of a copperish cast. The eyes are very prominent, and give the head a broad appearance. The thorax is angular, and

narrower than the head, which constitutes the character of the cicindela. It is rough, and of a green colour tinged with gold, as well as the head. The elytra are delicately and irregularly dotted. Each of them has six white spots, viz. one on the top of the elytrum, at its outward angle; three more along the outward edge, of which the middlemost forms a kind of lunula; a fifth on the middle of the elytra, opposite the lunula; and that one is broader, and tolerably round; lastly, a sixth at the extremity of the elytra. There is also sometimes seen a black spot on the middle of each elytrum, opposite to the second white spot. The upper lip is also white, as is the upper side of the jaws, which are very prominent and sharp. This insect runs with great swiftness, and flies easily. It is found in dry sandy places, especially in the beginning of spring. In the same places its larva is met with, which resembles a long, soft, whitish worm, furnished with six legs, and a brown scaly head. It makes a perpendicular round hole in the ground, and keeps its head at the entrance of the hole to catch the insects that fall into it; a spot of ground is sometimes entirely perforated in this manner. The insects belonging to this genus are in general very beautiful, and merit the attention of the curious in their microscopic observations; some are minute, though not inferior in splendour, therefore best suited for the experiment. Living subjects are ever preferable to dead ones. The larvæ of all this genus live under ground; and are, as well as the perfect insects, tigers in their nature, attacking and destroying all they can overcome.

CICUTA, *water hemlock*, a genus of the order digynia, in the pentandria class of plants, and ranking in the natural method under the 45th order, umbellatæ. There are three species, viz.

1. Cicuta bulbifera;
2. Cicuta maculata; and
3. Cicuta virosa. This species is the only one remarkable, and that from the poisonous qualities of its roots, which have been often known to destroy children who eat them for parsnips.

CIDARIS, in antiquity, the mitre used by the Jewish high-priests. The rabbis say, the bonnet used by the priests in general, was made of a piece of linen cloth sixteen yards long, which covered their heads like a helmet or a turban; and they allow no other difference between the high-priest's bonnet, and that of other priests, than this: that one is flatter, and more in the form of a turban; whereas that worn by ordinary priests rose something more in a point. A plate of gold was an ornament peculiar to the high-priest's mitre.

CILIARE, or *ligamentum ciliare*, or *ciliaris processus*, in anatomy, a range of black fibres disposed circularly, having their rise in the inner part of the uvea, and terminating in the prominent part of the chrystalline humour of the eye, which they surround. See ANATOMY.

CIMEX, or *bug*, in zoology, a genus of insects belonging to the order of hemiptera. (See Plate XXXIII. Nat. Hist. figs. 125. 126. 127.) The rostrum is inflected. The antennæ are longer than the thorax. The wings are folded together crosswise: the upper ones are coriaceous from their base towards their middle. The back is flat: the thorax margined. The feet are formed for running. This genus is divided into different sections, viz. 1. Those without wings. 2. Those in which the escutcheon is extended so far as to cover the abdomen and the wings. 3. The coleoptrati, whose elytra are wholly coriaceous. 4. Those whose elytra are membranaceous: these are very much depressed like a leaf. 5. In which the thorax is armed on each side with a spine. 6. Those which are of an oval form, without spines on the thorax. 7. In which the antennæ become setaceous towards their point. 8. Those of an oblong form. 9. Those whose antennæ are setaceous, and as long as the body. 10. Those that have their thighs armed with spines. 11. Those whose bodies are long and narrow. Linnæus enumerates no fewer than 121 species, to which several have been added by other naturalists. A very peculiar species was discovered by Dr. Sparman at the Cape, which he has named cimex paradoxus. He observed it as at noontide he sought for shelter among the branches of a shrub from the intolerable heat of the sun. "Though the air (says he) was extremely still and calm, so as hardly to have shaken an aspen leaf, yet I thought I saw a little withered, pale, crumpled leaf, eaten as it were by caterpillars, flittering from the tree. This appeared to me so very extraordinary, that I thought it worth my while suddenly to quit my verdant bower in order to contemplate it: and I could scarcely believe my own eyes, when I saw a live insect, in shape and colour resembling the fragment of a withered leaf, with the edges turned up, and eaten away as it were by caterpillars, and at the same time all over beset with prickles. Nature, by this peculiar form, has certainly extremely well defended and concealed, as in a mask, this insect from birds and its other diminutive foes; in all probability with a view to preserve it, and employ it for some important office in the system of her economy; a system with which we are too little acquainted, in general too little investigated; and which, in every part of it, can never sufficiently admire with that respect and veneration which we owe to the great Author of Nature and ruler of the universe."

The larvæ of bugs only differ from the perfect insect by the want of wings: they run over plants; and grow and change to chrysalids, without appearing to undergo any material difference. They have only rudiments of wings, which the last transformation unfolds, and the insect is then perfect. In the first two stages they are unable to propagate their species. In their perfect state, the female, fecundated, lays a great number of eggs, which are often found upon plants, placed one by the side of another; many of which, viewed through a glass, present singular varieties of configuration. Some are crowned with a row of small hairs, others have a circular fillet; and most have a piece which forms a cap; this piece the larva pushes off when it forces open the egg. Released by nature from their prison, they overspread the plant on which they feed, extracting, by the help of the rostrum, the juices appropriated for their nourishment: even in this state, the larvæ are not all peaceably inclined: some are voracious in an eminent degree, and spare neither sex nor species they can conquer. In their perfect state they are mere cannibals, glutting themselves with the blood of animals; they destroy caterpillars and flies; and even the coleopterous tribe, whose hardness of elytra one would imagine was proof against their attacks, have fallen an easy prey to the sharp

piercing nature of the rostrum of the bug, and the incautious naturalist may even experience a feeling severity of its nature. The cimex lectularius, or house-bug, is particularly acceptable to the palate of spiders in general, and is even sought after by wood-bugs; which is not indeed surprising, when the general voracity of this genus is considered. Trials have been made of various methods of destroying house-bugs, with oil of turpentine, camphor, solutions of sublimate, &c.

CIMICIFUGA, in botany, a genus of the polyandria order, in the diœcia class of plants. The male calyx is almost pentaphyllous; there is no corolla; the stamina are 20 in number: the female calyx is almost pentaphyllous; no corolla: the stamina 20, and barren; the capsules from four to seven, polyspermous. There is but one species; of which Messerschmidius, in the Isis Siberica, gives the following character and name: cimicifuga fœtida, with the leaves of the herb Christopher, bearing a thyrsus of yellow male flowers with a red villous seed, the seed-vessel in form of a horn. This whole plant so resembles the actea racemosa, that it is difficult to distinguish them when not in flower; but in the fructification it greatly differs from it, the cimicifuga having four pistils, the actea but one. Jacquin says, that it is a native of the Carpathian mountains. It has obtained the name of cimicifuga, or bugbane, both in Siberia and Tartary, from its property of driving away those insects: and the botanists of those parts of Europe which are infested by them, have long desired to naturalize it in their several countries. Gmelin mentions, that in Siberia the natives also use it as an evacuant in dropsy; and that its effects are violently emetic and drastic.

CIMOLIA *alba*, the name of the earth of which tobacco-pipes are made. Its distinguishing characters are, that it is a dense, compact, heavy earth, of a dull colour, and very close texture; it will not easily break between the fingers, and slightly stains the fingers in handling. It adheres to the tongue, melts slowly in the mouth, and is not readily diffusible in water. It is found in the Isle of Wight, Dorsetshire, and Staffordshire.

CIMOLIA *nigra*, is of a dark lead-colour, hard, dry, and heavy; it does not stain the hands, and is not acted upon by the acids. It burns perfectly white, and acquires a great degree of hardness. It is found in Northamptonshire, where it is used in the manufacture of pipes.

CIMOLITE, a species of white earth, found in some of the Grecian islands, where it is used for whitening stuffs. It is mentioned by Pliny under the name of cimolia, and in more modern authors it is called cimolia terra. Colour pearl-grey; when exposed to the air it becomes reddish. Texture earthy, fracture uneven, opaque, does not stain, but adheres strongly to the tongue. It is soft, and broken with difficulty: specific gravity is 2.000; and it becomes white before the blow-pipe. It is composed, according to Klaproth, of

63.00 silica,
23.00 alumina,
1.25 iron,
12.00 water.

99.25

CINCHONA, a genus of the monogynia order, in the pentandria class of plants, and in the natural method ranking with those plants, the order of which is dubious. The corolla is funnel-shaped, with a woolly summit; the capsule inferior, bilocular, with a parallel partition. There are nine species. The principal are,

1. Cinchona corymbifera, corymb-bearing cinchona, or white Peruvian bark, with oblong lanceolate leaves and axillary corymbs. This species particularly abounds in the hilly parts of Quito, growing promiscuously in the forests, and is spontaneously propagated from its seeds.

2. Cinchona caribæa, a native of the West India islands. In Jamaica it is called the sea-side beech, and grows from 20 to 40 feet high. The white, furrowed, thick, outer bark, is not used; the dark-brown inner bark has the common flavour, with a mixed taste, at first of horse-radish and ginger, becoming at last bitter and astringent. It seems to give out more extractive matter than the cinchona officinalis. Some of it was imported from St. Lucia, in consequence of its having been used with advantage in the army and navy during the last war.

3. Cinchona officinalis, or coloured Peruvian bark, with elliptic leaves, downy underneath, and the leaves of the corolla woolly. Both the corymbifera and officinalis are natives of Peru, where they attain the height of from 15 to 20 feet. The bark has an odour, to some people not unpleasant, and very perceptible in the distilled water; in which floating globules, like essential oil, have been observed. Its taste is bitter and astringent, accompanied with a degree of pungency, and leaving a considerably lasting impression on the tongue. For its properties and preparations, see PHARMACY.

CINCTURE, or *ceinture*, in architecture, a ring, list, or orlo, at the top and bottom of the shaft of a column, separating the shaft at one end from the base, and at the other from the capital. That at the bottom is particularly called apophyge, as if the pillar took its rise from it; and that at top colarin, collar, or collier, and sometimes annulus.

CINERARIA, a genus of the class and order syngenesia polygamia superflua. The calyx is simple, many-leaved, equal; pappus simple; receptacle naked. There are 41 species, most of them ornamental plants, and natives of the Cape; of which the C. cruenta, and the C. amelloides and lanata, are old and elegant ornaments of our greenhouses. The last has only one unpleasant property, that it is apt to be lousy.

[*Cinna*, a genus of the digynia order in the monandria class of plants. The characterestics are the calix, 2 valved, 1 floret; corolla 2 valved, 1 seeded, cylindrical. A native of Pennsylvania. Flowers in June. (*a*)

CINNABAR. See CHEMISTRY.

CINNAMON-TREE. See LAURUS.

No cinnamon can be imported into Britain except from the East Indies. That which comes thence pays a duty of 3*s*. $\frac{86}{100}$*d*. a pound, and draws back on exportation, 3*s*. $\frac{29\frac{1}{2}}{100}$*d*. at the rate of 6*s*. 8*d*.

Cinnamon is an astringent in the *primæ viæ*, but in the more remote seats of action it operates as an aperient and alexipharmic. It stops diarrhœas, strengthens the viscera, assists concoction, dispels flatulencies, and is a very pleasant cardiac. It affords an oil which will sink in water; and is in great esteem, and much prescribed in extemporaneous practice. As it is much adulterated on

account of its dearness, the best way to know it is by dropping it upon sugar, and then dissolving it in small spirit. This oil has been made genuine in England from the common cinnamon of the shops, so as to exceed that brought from Holland.

CINNAMON-WATER is made by distilling the bark first infused in spirit of wine, brandy, or white wine.

CINQUE-FOIL. See POTENTILLA.

CINQUE-PORTS were thus called by way of eminence, on account of their superior importance, as having been thought to merit a particular regard by the kings of England, for their preservation against invasion. Hence they have a particular policy; and are governed by a keeper, with the title of lord warden of the cinque ports. The five ports are, Hastings, Romney, Hythe, Dover, and Sandwich. Thorn tells us, that Hastings provided 21 vessels, and in each vessel 21 men. To this port belong Seaford, Pevensey, Hedney, Winchelsea, Rye, Hamine, Wakesbourne, Crencth, and Forthelipe. Romney provided five ships, and in each 24 men. To this belong Bromhal, Lyde, Oswarstone, Dangemares, and Romenhal. Hythe furnished five ships, and in each 21 seamen. To this belongs Westmeath. Dover the same number as Hastings. To this belong Folkstone, Feversham, and Marge. Sandwich furnished the same number with Hythe. To this belong Fordiwic, Reculver, Serre, and Deal. The privileges granted to them in consequence of these services were very great. Amongst others, they were each of them to send two barons to represent them in parliament; their deputies were to bear the canopy over the king's head at the time of his coronation, and to dine at the uppermost table in the great hall on his right hand; to be exempted from subsidies and other aids; their heirs to be free from personal wardship, notwithstanding any tenure; to be impleaded in their own towns only, and not to be liable to tolls, &c.

Certioraris, to remove indictments taken in the cinque-ports, must be directed to the mayor and jurats before whom they were taken, and not to the lord warden; because they hold plea of it as justices of the peace, by virtue of their commission, and not by their ancient character.

CIPHER, denotes certain secret characters disguised and varied, used in writing letters that contain some secret, not to be understood but by those between whom the cipher is agreed on. There are several kinds of ciphers, according to lord Bacon; as the simple, those mixed with non-significants, those consisting of two kinds of characters, wheel-ciphers, key-ciphers, word-ciphers, &c. They ought all to have these three properties, 1. They should be easy to write and read. 2. They should be trusty and undecipherable. 3. Clear of suspicion.

There is a new way of eluding the examination of a cipher, viz. to have two alphabets, the one of significant, and the other of non-significant letters; and folding up two writings together, the one containing the secret, while the other is such as the writer might probably send without danger: in case of a strict examination, the bearer is to produce the non-significant alphabet for the true, and the true for the non-significant; by which means the examiner would fall upon the outward writing, and finding it probable, suspect nothing of the inner. No doubt the art of ciphering is capable of great improvement. It is said that king Charles I. had a cipher consisting only of a straight line differently inclined: and there are ways of ciphering by the mere punctuation of a letter, whilst the words of a letter shall be non-significants, or sense that leaves no room for suspicion. Those who desire a fuller explanation of ciphering may consult Bacon, where they will find a cipher of his invention; bishop Wilkin's Secret and Swift Messenger; and Mr. Falconer's Cryptomenysis Patefacta.

CIPPUS, in antiquity, a low column, with an inscription, erected in the high roads, or other places, to show the way to travellers, to serve as a boundary, to mark the grave of a deceased person, &c. Those erected in the highways to mark the miles were called miliary columns.

CIRCÆA, *enchanter's nightshade*, a genus of the monogynia order, in the diandria class of plants, and in the natural method ranking under the 48th order, aggregatæ. The corolla is dipetalous; the calyx diphyllous, superior, with one bilocular seed. There are two species, one of which is a native of Britain, and the other of Germany. They are low herbaceous plants with white flowers, and possessed of no remarkable property.

[CIRCLE, in geometry, is a plane figure bounded by a curve line, called the circumference, or periphery; any point in which is equidistant from a point within the figure, called the centre.

The quadrature and rectification of the circle are problems which have exercised the abilities of some of the most eminent mathematicians in former times, and has been a cause of dispute among some of the less profound, down to the present day. But though neither of these have been effected precisely, they have been approximated to, and series have been given by which we may approximinate to them to any assigned degree of accuracy; and if the true value was not desirable we need not wish for a greater degree of accuracy. If the ratio of the diameter to the circumference were known, these problems, by the known properties of the circle, become very simple: this ratio was given by Archimedes to be $\frac{22}{7}$ nearly, which he effected in the following manner: he found the perimeter of a circumscribed regular polygon of 192 sides is to the diameter in a less ratio than $\frac{1}{7}\frac{0}{0}$ to 1, and that the perimeter of an inscribed regular polygon of 96 sides is to the diameter in a greater ratio than $\frac{1}{7}\frac{0}{1}$ to 1, therefore, he inferred the above ratio to be very near the truth; but this method, as we increase the number of sides of the polygon, evidently approaches to the area and circumference of the circle; yet it becomes tedious in proportion to the number of sides and the degree of accuracy required in the decimals.

Since the invention of fluxions, there have been a variety of series found, by which we approximate with ease to any assigned degree of accuracy—the following is a specimen of this method: Let r = radius, y = sine, and x = the versed sine of an arc z of a circle: then, $\overline{2r-x}\times x=y^2$, by the nature of the circle, and $x=r+(r^2-y^2)^{\frac{1}{2}}$, hence $dx=-ydy\times(r^2-y^2)^{-\frac{1}{2}}$. But $dz=(dx^2+dy^2)^{\frac{1}{2}}$, the general expression for the differential, or fluxion, of the length of the curve z. By substitution, $dz=rdy\times(r^2-y^2)^{-\frac{1}{2}}$, which put into an infinite series

gives $dz = rdy \times \left(\frac{1}{r} + \frac{y^2}{2r^3} + \frac{3y^4}{8r^5} + \frac{5y^6}{16r^7} + \frac{35y^8}{128r^9} + \text{&c.}\right)$; the integral, or fluent, of which is

$z = y \times \left(1 + \frac{y^2}{6r^2} + \frac{3y^4}{40r^4} + \frac{5y^6}{112r^6} + \frac{35y^8}{1152r^8} + \text{&c.}\right)$ Put t = the tangent of the arc z, then $y = \frac{tr}{(r^2+t^2)^{\frac{1}{2}}}$. And the preceding equation by substitution becomes

$z = t - \frac{t^3}{3r^2} + \frac{t^5}{5r^4} - \frac{t^7}{7r^6} + \frac{t^9}{9r^8} - \text{&c.}$ = the length of the arc in terms of the tangent. Suppose $r=1$ and the arc = 45°, whose tangent = radius = 1; then the series is $z = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \frac{1}{13} - \frac{1}{15} + \text{&c.}$ = the length of an arch of 45°; therefore,

$8 \times \left(1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \frac{1}{13} - \frac{1}{15} + \text{&c.}\right)$ equal the whole circumference to a diameter 2, therefore,

$4 \times \left(1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \frac{1}{13} - \frac{1}{15} + \text{&c.}\right) =$ 3.141592 &c. the circumference to a diameter unity; consequently by the known property of the circle 3.141592 ÷4=.785398 &c. equals the area of a circle to diameter unity. (*r*)

CIRCLE of the higher kind, an expression used by Wolfius, and some others, to denote, for the most part, a curve expressed by the equation $y^m = ax^{m-1} - x^m$; which indeed will be an oval when m is an even number; but when m is an odd number, the curve will have two infinite legs.

CIRCLES, *druidical*, in British topography, a name given to certain ancient inclosures, formed by rude stones, circularly arranged.

These, it is now generally agreed, were temples, and many writers think also places of solemn assemblies for councils or elections, and seats of judgment. These temples, though generally circular, occasionally differ as well in figure as magnitude: with relation to the first, the most simple were composed of one circle. Stonehenge consisted of two circles and two ovals, respectively concentric; whilst that at Bottalch near St. Just in Cornwall is formed by four intersecting circles. The great temple at Abury in Wiltshire, it is said, described the figure of a seraph or fiery flying serpent, represented by circles and right lines. Some, besides circles, have avenues of stone pillars. Most, if not all of them, have pillars or altars within their penetralia or centre. In the article of magnitude and number of stones, there is the greatest variety; some circles being only 12 feet diameter, and formed only of 12 stones; whilst others, such as Stonehenge and Abury, contained, the first 140, and the second 652, and occupied many acres of ground. All these different numbers, measures, and arrangements, had their pretended reference, either to the astronomical divisions of the year, or some mysteries of the druidical religion.

CIRCONCELLIONES, a race of fanatics, so called because they were continually rambling round the houses in the country. They took their rise among the donatists in the reign of the emperor Constantine. It is incredible what ravages and cruelties these vagabonds committed in Africa through a long series of years. They were illiterate, savage peasants, who understood only the Punic language. Intoxicated with a barbarous zeal, they renounced agriculture, professed continence, and assumed the title of "vindicators of justice, and protectors of the oppressed." To accomplish their mission, they enfranchised slaves, scoured the roads; forced masters to alight from their chariots, and run before their slaves, whom they obliged to mount in their place; and discharged debtors, killing the creditors if they refused to cancel the bonds. The counts Ursacius and Taurinus were employed to quell them: they destroyed a great number of them, of whom the donatists made as many martyrs. Ursacius, who was a good catholic, and a religious man, having lost his life in an engagement with the barbarians, the donatists did not fail to triumph in his death, as an effect of the vengeance of heaven. Africa was the theatre of these bloody scenes during a great part of Constantine's life.

CIRCUIT, or CIRCUITY, in law, signifies a longer course of proceedings than is needful to recover the thing sued for: in case a person grants a rent-charge of 10*l.* a year of his manor, and afterwards the grantee disseises the grantor, who thereupon brings an assise, and recovers the land, and 20*l.* damages; which being paid, the grantee brings his action for 10*l.* of the rent, due during the time of his disseisin. This is termed circuity of action, because as the grantor was to receive 20*l.* damages, and pay 10*l.* rent, he might only have received 10*l.* for the damages, and the grantee might have retained the other 10*l.* for his rent, and by that means saved his action.

CIRCUIT also signifies the journey or progress which the judges take twice every year through the several counties of England and Wales, to hold courts and administer justice, where recourse cannot be had to the king's court at Westminster. Hence England is divided into six circuits, viz. the home circuit, Norfolk circuit, midland circuit, Oxford circuit, western circuit, and northern circuit. In Wales there are but two circuits, north and south Wales: two judges are assigned by the king's commission to every circuit. In Scotland there are three circuits, viz. the southern, western and northern, which are likewise made twice every year, viz. in spring and autumn.

CIRCULAR *sailing*, is the method of sailing by the arch of a great circle. See NAVIGATION.

CIRCULAR *velocity*, in astronomy, signifies the velocity of any planet or revolving body, which is measured by the arch of a circle.

CIRCULATION *of the blood*. See PHYSIOLOGY.

CIRCUMFERENCE, the curve line which bounds a circle; and otherwise called a periphery, the boundary of a right-lined figure being expressed by the term perimeter. Any part of the circumference is called an arch, and a right line drawn from one extreme of the arch to the other is called a chord. The circumference of every circle is supposed to be divided into 360 degrees. The

angle at the circumference of a circle is double that at the centre.

CIRCUMFERENTOR, an instrument used by surveyors for taking angles. See Surveying.

CIRCUMSCRIBED, in geometry, is said of a figure which is drawn round another figure, so that all its sides or planes touch the inscribed figure.

Circumscribed *hyperbola*, one of sir Isaac Newton's hyperbolas of the second order, that cuts its asymptotes, and contains the parts cut off within its own space.

CIRCUMSCRIBING, in geometry, denotes the describing a polygonous figure about a circle, in such a manner that all its sides shall be tangents to the circumference. Sometimes the term is used for the describing a circle about a polygon, so that each side is a chord; but in this case it is more usual to say the polygon is inscribed, than the circle is circumscribed.

CIRCUMSTANTIBUS, in law, a term used for supplying and making up the number of jurors (in case any impannelled appear not; or appearing, are challenged by either party), by adding to them so many of the persons present as will make up the number, in case they are properly qualified.

CIRCUMVALLATION, or line of circumvallation, in military affairs, implies a fortification of earth, consisting of a parapet and trench, made round the town intended to be besieged, when any molestation is apprehended from parties of the enemy, which may march to relieve the place. Care is to be taken to have the most exact plan of it possible; and upon this the line of circumvallation and the attack are projected. This line, being a fortification opposed to an enemy that may come from the open country to relieve the besieged, ought to have its defences directed against them; that is, so as to fire from the town; and the besiegers are to be encamped behind this line, and between it and the place. The camp should be as much as possible out of the reach of the shot of the place; and the line of circumvallation, which is to be farther distant than the camp, ought still more to be out of the reach of its artillery.

As cannon are never to be fired from the rear of the camp, this line should be upwards of 1200 fathoms from the place; we will suppose its distance fixed at 1400 fathoms from the covert-way. The depth of the camp may be computed at about 30 fathoms; and from the head of the camp to the line of circumvallation 120 fathoms, that the army may have room to draw up in order of battle at the head of the camp, behind the line. This distance added to the 30 fathoms makes 150 fathoms, which being added to the 1400, makes 1550 fathoms to constitute the distance of the line of circumvallation from the covert-way. The top of this line is generally 12 feet broad, and seven feet deep. The parapet runs quite round the top of it, and at certain distances is frequently strengthened with redoubts and small forts: the base 18 feet wide, the height within six, and on the outside five feet, with a banquette of three feet wide and one and a half high.

CIRCUS, in antiquity, a great building of a round or oval figure, erected by the ancients, to exhibit shows to the people. The Roman circus was a large oblong edifice, arched at one end, encompassed with porticoes, and furnished with two rows of seats placed ascending over each other. In the middle was a kind of foot-bank, or eminence, with obelisks, statues, and posts, at each end. This served them for the courses of their bigæ and quadrigæ. Those that have measured the circus say that it was 2187 feet long, and 960 broad; so that it was the greatest building in Rome. Some say it would contain 150,000 people, others 260,000 or 300,000. The circus was dedicated to the sun, as a little temple of the sun in the middle denoted. Some say that there were eight circuses in Rome, of which several were, either through vanity or devotion, built for the ornament of the city.

CIRRI, among botanists, fine strings or thread-like filaments, by which some plants fasten themselves to walls, trees, &c. Such are those of ivy.

Cirri in ichthyology, certain oblong and soft appendages, not unlike little worms, hanging from the underjaws or mouths of some fishes. These cirri, commonly translated beards, afford marks to distinguish the different species of the fish on which they are found. Their use may be to give notice of approaching danger or prey; since by their hanging position, as well as by their soft texture, they must be more sensible of any motion in the water than any other part.

CIRSOCELE, or Hernia varicosa. See Surgery.

CISSAMPELOS, a genus of the monadelphia order, in the diœcia class of plants; and in the natural method ranking under the 11th order, sarmentaceæ. The male calyx is tetraphyllous; no corolla; the nectarium wheel-shaped; four stamina with their filaments grown together. The female calyx is monophyllous and ligulated, roundish, or like a piece of garter a little roundish. There is no corolla; three styles, and a monospermous berry. There are five species: the

Cissampelos caapeba is a native of the warmest parts of America. The root applied externally is said to be an antidote against the bites of venomous serpents. The plant being infused in water, quickly fills the liquor with a mucilaginous substance, which is as thick as jelly; whence the name of freezing wyth, by which this genus of plants has been distinguished by the Brazilians.

CISSOID, in geometry, a curve of the second order, first invented by Diocles, whence it is called the cissoid of Diocles.

Sir Isaac Newton, in his appendix de æquationum constructione lineari, gives the following elegant description of this curve; and at the same time shows how, by means of it, to find two mean proportionals, and the roots of a cubic equation, without any previous reduction. Let AG (Plate XXXIX. Miscel. fig. 14) be the diameter, and F the centre of the circle belonging to the cissoid; and from F draw FD, FP, at right angles to each other, and let FP be =AG; then if the square PED be so moved that one side EP always passes through the point P, and the end D of the other side ED slides along the right line FD, the middle point C of the side ED will describe one leg GC of the cissoid; and by continuing out ED on the other side F, and turning the square about by a like operation, the other leg may be described.

This curve may likewise be generated by points in the following manner. Draw the indefinite right line BC (fig. 15) at right angles to AB the diameter of the

semicircle AOB, and draw the right lines AH, AF, AC, &c. then if you take AM=LH, AO=OF. ZC=AN, &c. the points MOZ, &c. will form the curve AMOZ of the cissoid.

Properties of the Cissoid.—It follows from the genesis, that drawing the right lines PM, KL. perpendicular to AB, the lines AK, PN, AP, PM, as also AP. PN, AK, KL, are continual proportionals. and therefore that AK=PB, and PN=LK. If the diameter AB=a, the abscise AP=x, and the ordinate PM=y, then is $x : a - x :: y^2 : x^2$ or $x^3 = a - x \times y^2$, which is the equation of the curve. After the same manner it appears that the cissoid AMO, bisects the semicircle AOB. Sir Isaac Newton, in his last letter to Mr. Leibnitz, has shown how to find a right line equal to one of the legs of this curve, by means of the hyperbola, but suppressed the investigation, which however may be seen in his Fluxions. The cissoidal space contained under the diameter AB, the asymptote BC, and the curve AOZ of the cissoid, is triple that of the generating circle AOB. See Dr. Wallis's mathematical works, Vol. I. p. 545, et seq.

CISSUS, the wild grape, a genus of the monogynia order, in the tetrandria class of plants, and in the natural method ranking under the 46th order, hederaceæ. The berry is monospermous, surrounded by the calyx, and a quadripartite corolla. There are 15 species, natives of Jamaica, and some of the other islands in the warmest parts of America and the East Indies. They send out slender branches, having tendrils at their joints; by which they fasten to the neighbouring trees, bushes, and any other support, mounting to a considerable height. The fruit of some of the species is eaten by the negroes.

CISTERCIANS, in church-history, a religious order founded in the eleventh century by St. Robert, a benedictine. They became so powerful, that they governed almost all Europe, both in spirituals and temporals. Cardinal de Vitri describing their observances says, they neither wore skins nor shirts, nor ever eat flesh except in sickness; and abstained from fish, eggs, milk, and cheese. They lay upon straw beds, in their tunics and cowls: they rose at midnight to prayers; they spent the day in labour, reading, and prayer; and in all their exercises observed a continual silence. The habit of the Cistercian monks is a white robe, in the nature of a cassock, with a black scapulary and hood, and is girt with a wollen girdle. The nuns wear a white tunic, and a black scapulary and girdle.

CISTUS, rockrose, a genus of the monogynia order, in the polyandria class of plants, and in the natural method ranking under the 20th order, rotaceæ. The corolla is pentapetalous; the calyx pentaphyllous, with two of its leaves smaller than the rest. The seeds are contained in a capsule. There are 66 species, most of them natives of the southern parts of Europe, but many of them hardy enough to bear the open air in this country. They are beautiful evergreen shrubs, generally very branchy quite from the bottom, and forming diffused heads. They are very ornamental in gardens: not only as evergreens, making a fine variety at all seasons with the leaves of different figures, sizes, and shades of green and white; but also as first-rate flowering shrubs, being very profuse in most elegant flowers of white, purple, and yellow colours. These flowers last only for one day; but there is a continual succession of new ones for a month or six weeks on the same plant; and when there are different species, they exhibit a constant bloom for near three months. They are propagated either by seeds or cuttings, and thrive best in a dry soil. Their proper situation in shrubbery works should be towards the front of the clumps and other compartments, in assemblage with the choicest shrubs of similar growth, disposing them so as to make a variety, and to have shelter from the other plants, but they ought by no means to be crowded. Gum labdanum is found upon a species of cistus which grows naturally in the Levant, and is therefore called labdaniferus.

CITADEL, a place fortified with four, five, or six bastions, built on a convenient ground near a city, that it may command it in case of a rebellion. The city therefore is not fortified on the part opposite to the citadel; though the citadel is against the city. The best form for a citadel is a pentagon, a square being too weak, and a hexagon too large.

CITATION, in ecclesiastical courts, is the same with summons in civil courts. A person is not to be cited out of the diocese where he lives, unless it be by the archbishop in default of the ordinary, or where the ordinary is party to the suit, and in case of appeal.

CITHAREXYLUM, fiddle-wood, a genus of the angiospermia order, in the didynamia class of plants, and in the natural method ranking under the 40th order, personatæ. The calyx is quinquedentated, campanulated, wheel-shaped, with its segments villous, on the upper side equal. The fruit is a dispermous berry; the seeds bilocular. There are five species, natives of the warmer parts of America, where they grow to be large trees, and are adorned with white flowers growing in spikes. In Britain they appear only as shrubs, and must be constantly retained in the stove, where they make a fine appearance, being beautiful evergreens. They may be propagated either by seeds or cuttings.

CITRINUS, in natural history, a peculiar species of sprig crystal, which is of a beautiful yellow. Many of the common crystals, when in the neighbourhood of lead mines, are liable to be accidentally tinged yellow, by an admixture of the particles of that metal; and all these, whether finer or coarser, have been too frequently confounded together under the name citrine; but Dr. Hill has ascertained this to be a peculiar species of crystals different from all the others in form as well as in colour; and distinguished by the name of ellipomacrostylum lucidum flavescens, pyramido brevi. It is never found colourless like the other crystals, but has great variety of tinges, from that of the deeper ochres to a pale lemon-colour. It is sometimes found in Bohemia. The pyramid of this crystal is always finer than the column.

CITRUS, the citron, orange, and lemon tree, a genus of the polyadelphia class and the icosandria order of plants. The calyx is quinquefid; the petals oblong, and five in number; the anthers are 20. filaments united into various bodies; fruit nine-celled. There are five species, with many varieties, viz.

1. Citrus aurantium, the orange: of which the varieties are, 1. Seville orange. This is a very handsome tree, and the hardiest of any; as in this country it shoots freely, produces large and beautiful leaves, flowers stronger,

&c. The fruit is large, rough-rinded, and sour, of excellent quality for economical uses. 2. The China orange. This tree has moderately-sized leaves, and a smooth, thin-rinded, sweet fruit, of which there are several varieties in warm countries, where they grow in the open ground. 3. The forbidden-fruit tree, in trunk, leaves, and flowers, very much resembles the common orange-tree; but the fruit when ripe is larger and longer than the biggest orange. (See Plate.) It has somewhat the taste of shaddock, but far exceeds that, as well as the best orange, in its delicious taste and flavour. 4. The horned orange is a tree of moderate size, producing fruit which divide, and the rind runs out into divisions like horns. 5. The hermaphrodite orange is a common sized tree, producing fruit shaped partly like an orange and partly like a citron. 6. The dwarf orange tree, or nutmeg orange, has a long stem and small bushy head, growing two or three feet high; small oval leaves in clusters; and numerous flowers in clusters, covering the branches, succeeded by very small fruit.

2. Citrus medica, the citron tree. The varieties are, 1. citron-tree with sour fruit; 2. with sweetish fruit; 3. with long fruit; 4. with warted fruit; 5. with recurved fruit; and 6. with blotched leaves.

The lemon-tree is accounted a variety of the citron. The varieties of lemon are, 1. the lemon-tree with sour fruit; 2. with sweetish fruit; 3. with very large fruit, called imperial lemon; 4. with pear-shaped fruit; 5. with furrowed fruit; 6. with clustered fruit; 7. with childing fruit; 8. with whitish fruit; 9. with tricolar striped fruit; 10. with silver-striped leaves; and 11. with double flowers.

These are the most remarkable varieties of the species of citrus; but besides these there are a great number of others; and indeed in those countries where they grow naturally, the varieties may be multiplied without end, like those of our apples and pears. The flowers of all the species and varieties are formed each of five spreading petals, appearing here principally in May and June, and the fruit continues setting in June and July, and ripens the year following.

3. Citrus trifoliata, is a thorny shrub growing naturally in Japan, where it is likewise known by the names of gees, and karatals hanna. The trunk acquires by age and culture the thickness of a tree. The flowers, which resemble those of the medlar, proceed singly from the arm-pits of the leaves, are white, possessed of no great degree of fragrance, and consist of five petals. The fruit is equally beautiful with a middle-sized orange; their internal structure is also pretty much the same; only the pulp is glutinous, of an unpleasant smell, and a harsh disagreeable taste. The seeds have the same taste with the pulp, and are shaped exactly like those of the orange.

4. Citrus decumana, or shaddock, which derives its name from captain Shaddock, who brought it from the East to the West Indies.

5. Citrus japonica, the fruit of which is no larger than a cherry, but very sweet and pleasant.

CITIES, *imperial*, an appellation given to those cities of Germany immediately subject to the emperor: they make a part of the Germanic body, are governed by their own magistrates, have the privilege of coining money, and assist at the diet of the empire. They are 48 in all, and are distinguished in general by their prosperity and opulence.

CIVET. See Viverra.

CIVIL LAW, is properly the peculiar law of each state, country, or city; but what is usually meant by the civil law, is a body of laws composed out of the best Roman and Grecian laws, compiled from the laws of nature and nations, and for the most part received and observed throughout all the Roman dominions for above 1200 years.

The Romans took the first grounds of this law from the twelve tables; which were abridgments of the laws of Solon, at Athens, and of other celebrated cities of Greece; to which they added their own ancient customs of the city of Rome. These written laws were subject to various interpretations, whence controversies arising, they were determined by the judgment of the learned; and these determinations were what they first called jus civile, after their several cases were composed, which, lest the people should make them at pleasure, were fixed, certain, and solemn; and this part of their law they called actions juris, cases at law. The Romans had also their plebicita, which were laws made by the commons, without the authority of the senate. The jus honorarium was an edict of some particular magistrate, the senatus consultum an ordinance made by the sole authority of the senate, and the principalis constitutio was enacted by the prince or emperor. These laws grew by degrees to a vast number of volumes, and therefore the emperor Justin an commanded his chancellor Trebonianus, with the assistance of some other eminent lawyers, to reduce them to a perfect body.

The body of the civil law is divided into three volumes, which are still remaining, viz. the pandects or digests, the code, and the institutes: to these were afterwards added he authenties or constitutions of Justinian, called also novellæ, or novels. See Code, &c.

The civil law is not received at this day in any one nation, without some addition or alteration. For sometimes the feudal law is mixed with it, or general or particular customs; and often ordinances and statutes cut off a great part of it. In Turkey the Justinian Greek code is only used. In Italy, the canon law and customs have excluded a good part of it. In Venice, custom has almost an absolute government. In the Milanese, the feudal law and particular customs bear sway. In Naples and Sicily, the constitutions and laws of the Lombards are said to prevail. In Germany and Holland, the civil law is esteemed to be the municipal law; but yet many parts of it are there grown obsolete, and others are altered, either by the canon law, or a different usage. In Friezland it is observed with more strictness; but in the northern parts of Germany, the jus Saxonicum, Lubecense, or Culmense, is preferred to it. In Denmark and Sweden it has scarcely any authority at all. In France only a part of it is received, and that part is in some places as a customary law; and in those provinces nearest to Italy, municipal written law. In criminal cases the civil law is more regarded in France: but the manner of trial is regulated by ordinances and edicts. The civil law in Spain and Portugal is corrected by the jus regium, and custom. In Scotland the statutes of the sederunt, part of the regiæ majestatis, and their customs,

controul the civil law. In England it is used in the ecclesiastical courts, in the courts of the admiralty, and in the two universities: yet in all these it is restrained and directed by the common law.

Civil year is the legal year, or annual account of time, which every government appoints to be used within its own dominions; and is so called in contradistinction to the natural year, which is measured by the revolution of the heavenly bodies.

CIVILIAN, in general, denotes something belonging to the civil law, but more especially the doctors and professors of it are called civilians. Of these there are a college or society in London, known by the name of doctors'-commons.

CLAIM, in law, a challenge of interest in any thing that is in the possession of another, or at least out of a man's own; as claim by charter, by descent, &c. By stat. 4 Anne c. 16. sect. 16. no claim or entry shall be of force to avoid any fine levied with proclamation in the common-pleas, or in the court of session in the counties palatine, or of grand session in Wales, or shall be a sufficient entry to claim within the statute of limitation, 21 Jac. 1. c. 16. unless upon such entry or claim, an action be commenced within one year after making such entry or claim, and prosecuted with effect. Plowd. 359.

CLAMP, *in a ship*, denotes a piece of timber applied to a mast or yard, to prevent the wood from bursting; and also a thick plank lying fore and aft under the beams of the first orlop, or second deck, and is the same that the rising timbers are to the deck.

Clamp is likewise the term for a pile of unburnt bricks built up for burning.

CLAMPING, in joinery, is the fitting a piece of board with the grain, to another piece of board cross the grain. Thus the ends of tables are commonly clamped; to prevent their warping.

CLANS, in history, and particularly in that of Scotland. The nations which overran Europe were originally divided into many small tribes; and when they came to parcel out the lands which they had conquered, it was natural for every chieftain to bestow a portion, in the first place, upon those of his own tribe or family. These all held their lands of him; and as the safety of each individual depended on the general union, these small societies clung together, and were distinguished by common appellation, either patronymical or local, long before the introduction of surnames or ensigns armorial. But when these became common, the descendants and relations of every chieftain assumed the same name and arms with him. Other vassals were proud to imitate their example; and by degrees they were communicated to all those who held of the same superior. Thus clanships were formed; and in a generation or two that consanguinity which was at first in a great measure imaginary, was believed to be real. An artificial union was converted into a natural one. Men willingly followed a leader, whom they regarded both as the superior of their lands and the chief of their blood, and served him not only with the fidelity of vassals, but the affection of friends. Against such men a king contended with great disadvantage; and that cold service which money purchases, or authority extorts, was not an equal match for their ardour and zeal. Some imagine the word clan to be only a corruption of the Roman colonia; but Mr. Whitaker asserts it to be purely British, and to signify a family.

CLARENCIEUX, the second king at arms, so called from the duke of Clarence, to whom he first belonged; for Lionel III. son to Edward III. having by his wife the honour of Clare, in the county of Thomond, was afterwards declared duke of Clarence; which dukedom afterwards escheating to Edward IV. he made this earl a king at arms. His office is to marshal and dispose of the funerals of all the lower nobility, as baronets, knights, esquires, on the south side of the Trent; whence he is sometimes called Surroy, or South-roy, in contradistinction to Norroy.

CLARENDON. The constitutions of Clarendon are certain ecclesiastical laws drawn up at Clarendon, near Salisbury. They were sixteen in number, all tending to restrain the power of the clergy; and readily assented to by all the bishops and barons, the archbishop Becket excepted, who opposed them at first, but was afterwards prevailed upon to sign them. The pope Alexander III. declared against and annulled most of them.

CLARIFICATION, in chemistry, the act of clearing and fining any fluid from all heterogeneous matter or feculancies. See Chemistry.

CLARION, a kind of trumpet, the tube of which is narrower, and its tone acuter and shriller, than that of the common trumpet. It is said that the clarion, now used among the Moors, and Portuguese who borrowed it from the Moors, served anciently for a treble to several trumpets, which sounded tenor and bass.

Clarion, in heraldry, a bearing as represented: he bears ruby, three clarions topaz, being the arms of the earl of Bath, by the name of Granville. Guillim is of opinion, that these three clarions are a kind of old fashioned trumpets; but others say that they rather resemble the rudder of a ship, others a rest for a lance.

CLARO-OBSCURO, or Clair-obscure, in painting, the art of distributing to advantage the lights and shadows of a piece, both with regard to the easing of the eye, and the effect of the whole piece. See Painting.

CLASS, an appellation given to the most general subdivisions of any thing: thus, in the Linnæan system, animals are divided into six classes, viz. mammalia, aves, amphibia, pisces, insecta, and vermes; these are again subdivided in orders, and these last into genera. See Natural History.

CLATHRUS, in botany, a genus of roundish fungi; the substance of which is reticulated, or full of holes, somewhat like the meshes of a net, with continuous ramification. There are seven species.

CLAVA, a genus of vermes mollusca, having one common aperture, dilatable, vertical, surrounded by club-shaped tentacula. There is only one species.

CLAVARIA, club-top, a genus of the cryptogamia class of plants, and of the order of fungi; the 58th in the natural method. The fungus is smooth and oblong. Mr. Miller asserts, that the whole genus of clavaria belongs to the tribe of zoophytes, that is, to the animal, and not to the vegetable kingdom. According to this method, he ranks them among the vermes, under a subdivision which he terms fungosa osculis atomiferis: supposing them to be compound animals with many orifices on their sur-

face, from which are protruded atoms or animalcules, which have a visible spontaneous motion, something similar to what is now acknowledged to be a fact, with regard to a numerous class of marine bodies, termed corallines. This motion, however, has not been observed by other naturalists. Schæffer has figured the seeds of several clavariæ as they appeared to him through the microscope; and none of these fungi, when burnt, emit the strong disagreeable smell peculiar to animal substances.

1. Clavaria hemotades, or the oak leather club-top, exactly resembles tanned leather, except that it is thinner and softer. It is of no determinate form. It grows in the clefts and hollows of old oaks, and sometimes on ash in Ireland and in some places of England, &c. In Ireland it is used to dress ulcers, and in Virginia to spread plasters upon, instead of leather.

2. Clavaria militaris, and one or two other species, are remarkable for growing only on the head of a dead insect in the nympha state.

CLAVARIUM, in antiquity, an allowance the Roman soldiers had for furnishing nails to secure their shoes with. They frequently raised mutinies, and demanded largesses of the emperors, under this pretence.

CLAVES INSULÆ, a term used in the Isle of Man, where all weighty and ambiguous causes are referred to a jury of twelve, who are called claves insulæ, the keys of the island.

CLAVICLES. See Anatomy.

CLAUSE-ROLLS, in the Tower, contain all such matters as were committed to close writ.

CLAVUS, in antiquity, an ornament upon the robes of the Roman senators and knights, which was more or less broad, according to the dignity of the person. Hence the distinction of tunica angusticlavia and laticlavia.

CLAW, among zoologists, denotes the sharp-pointed nails with which the feet of certain quadrupeds and birds are furnished.

CLAY, is a mixture of alumina and silica in various proportions. The alumina is in the state of an impalpable powder; but the silica is almost always in small grains, large enough to be distinguished by the eye. Clay therefore exhibits the character of alumina, and not of silica, even when this last ingredient predominates. The particles of silica are already combined with each other; and they have so strong an affinity for each other, that few bodies can separate them; whereas the alumina, not being combined, readily displays the characters which distinguish it from other bodies. Besides alumina and silica, clay often contains carbonat of lime, of magnesia, barytes, oxyd of iron, &c. and as clay is merely a mechanical mixture, the proportion of its ingredients is exceedingly various. Its specific gravity is 1.8 to 2.68. Adheres slightly to the tongue. Often feels greasy. Falls to powder in water. Colour, when pure, white, often tinged blue or yellow.

The specific gravity of potter's clay is 1.8 to 2. Stains the fingers slightly. Acquires some polish by friction. Colour white; often with a tinge of yellow or blue; sometimes brownish, greenish, reddish. Totally diffusible in water; and when duly moistened, very ductile. A specimen from Dreux, analysed by Vauquelin, contained

43.5	silica
33.2	alumina
3.5	lime
1.0	iron
18.0	water
99.2	

Very common in strata. Tobacco-pipe clay is a variety of this sub-species.

Indurated clay does not diffuse itself in water, but falls to powder. Discovers but little ductility. Colours grey, yellowish, bluish, greenish, reddish, brownish.

The structure of shistose clay is slaty. Specific gravity from 2.6 to 2.68. Feels smooth. Streak white or grey. Colour commonly bluish, or yellowish grey; sometimes blackish, reddish, greenish. Found in strata, usually in coal-mines. This variety is sometimes impregnated with bitumen. It is then called bituminous shale.

CLAYTONIA, in botany, a genus of the pentandria monogynia class of plants, the flower of which consists of five ovato-oblong, erect, large petals; the fruit is a roundish unilocular capsule, containing three roundish seeds. There are two species.

CLEAT, on ship-board, a piece of wood fixed to the yard-arm, to keep the ropes from slipping off.

CLECHE, in heraldry, a kind of cross, charged with another cross of the same figure, but of the colour of the field.

CLEF, or Cliff, in music, a mark set at the beginning of the lines of a song, which shows the tone or key in which the piece is to begin; or it is a letter marked on any line, which explains the rest.

CLEMATIS, virgin's bower, in botany, a genus of the polyandria polygynia class of plants, the flower of which consists of four oblong lax petals. There is no pericarpium, but a small receptacle contains several roundish compressed seeds, crowned with a slender filament, somewhat like a feather. There are 21 species, chiefly climbing shrubs. See Plate XXXIII. Nat. Hist. fig. 128.

CLEOME, a genus of the siliquosa order, in the tetradynamia class of plants, and in the natural method ranking under the 25th order, putaminæ. There are three nectariferous glandules, one at each sinus of the calyx, except the lowest; the petals all rising upwards; the siliqua unilocular and bivalved. There are 15 species; all natives of warm climates, except two. They are herbaceous plants, rising from one to two feet high; and are adorned with flowers of various colours, as red, yellow, flesh-colour, &c. They are propagated by seeds, and require no other care than what is common to other exotics which are natives of warm countries.

CLEPSYDRA, a water-clock, or instrument to measure time by the fall of a certain quantity of water.

The construction of a Clepsydra. To divide any cylindrical vessel into parts, to be emptied in each division of time; the time wherein the whole, and that wherein any part is to be evacuated, being given:—

Suppose a cylindrical vessel, whose charge of water flows out in twelve hours, was required to be divided into parts, to be evacuated each hour. 1. As the part of time 1 is to the whole time 12, so is the same time 12

to a fourth proportional 144. 2. Divide the altitude of the vessel into 144 equal parts: here the last will fall to the last hour; the three next above to the last part but one; the five next to the tenth hour; and so the twenty-three last will fall to the first hour. For since the times increase in the series of the natural numbers 1, 2, 3, 4, 5, &c. and the altitudes, if the numeration be in a retrograde order from the twelfth hour, increase in the series of the unequal numbers 1, 3, 5, 7, 9, &c. the altitudes computed from the twelfth hour will be as the squares of the times 1, 4, 9, 16, 25, &c. Therefore the square of the whole time, 144, comprehends all the parts of the altitude of the vessel to be evacuated. But a third proportional to 1 and 12 is the square of 12, and consequently it is the number of equal parts in which the altitude is to be divided, to be distributed according to the series of the unequal numbers, through the equal intervals of hours.

There were many kinds of clepsydræ among the ancients; but they all had this in common, that the water ran generally through a narrow passage, from one vessel to another; and in the lower was a piece of cork or light wood, which, as the vessel filled, rose up by degrees, and showed the hour. The reader may see a description of a very curious clepsydra given by Mr. Hamilton, in No. 479 of the Philosophical Transactions.

CLERGY. The privileges of the English clergy, by the ancient statutes, are very considerable: their goods are to pay no toll in fairs or markets; they are exempt from all offices but their own; from the king's carriages, posts, &c. from appearing at sheriff's tourns, or frankpledges; and are not to be fined or amerced according to their spiritual, but their temporal means. A clergyman acknowledging a statute, his body is not to be imprisoned. If he is convicted of a crime for which the benefit of clergy is allowed, he shall not be burnt in the hand; and he shall have the benefit of clergy in infinitum, which no layman can have more than once. The clergy, by common law, are not to be burdened in the general charges of the laity; nor to be troubled nor encumbered, unless expressly named and charged by the statute; for general words do not affect them. Thus if a hundred is sued for a robbery, the minister shall not contribute, neither shall they be assessed to the highway, to the watch, &c.

The revenues of the clergy were anciently more considerable than at present. Ethelwolf, in 855, gave them a tythe of all goods, and a tenth of all the lands in England, free from all secular services, taxes, &c. The charter whereby this was granted them was confirmed by several of his successors: and William the Conqueror, finding the bishoprics so rich, created them into baronies, each barony containing thirteen knight's fees at least; but since the Reformation the bishoprics are much impoverished. The revenues of the inferior clergy, in general, are small: a third part of the best benefices being anciently, by the pope's grant, appropriated to monasteries, upon the dissolution thereof became a lay-fee.

Clergy, *benefit of*, is an ancient privilege, whereby one in orders claimed to be delivered to his ordinary, to purge himself of felony. This purgation was to be by his own oath, affirming his innocence, and the oath of twelve compurgators, as to their belief of it, before a jury of twelve clerks: if the clerk failed in his purgation, he was deprived of his character, whereby he became a mere layman, or he was to be kept in prison till a pardon was obtained; but if he purged himself, he was set at liberty. This was formerly admitted, even in cases of murder; but the ancient course of the law is much altered upon this head. By the statute of 18 Eliz. cap. vii. clerks are no more committed to their ordinary to be purged; but every man to whom the benefit of clergy is granted, though not in orders, is put to read at the bar, after he is found guilty and convicted of such felony, and so burnt in the hand, and set free for the first time, if the ordinary or deputy standing by, do say, Legit ut clericus: otherwise he shall suffer death.

It appears by our law-books, that laymen that could read had the privilege of the clergy ever since 25 Edw. III. which allowance never was condemned in parliament, but rather approved of.

CLERK, a word originally appropriated to the clergy, from the Greek κληρος (chosen), whence it was afterwards applied to denote a learned man, or man of letters: in law it is still the designation of a clergyman, or a person in holy orders; in former times the nobility and gentry being usually bred up to the exercise of arms, and none left but the ecclesiastics to cultivate the sciences.

Clerk *of the acts*, an officer in the navy office, appointed for recording all orders, contracts, bills, warrants, &c. transacted by the lords of the admiralty and commissioners of the navy.

Clerk *of the affidavits*, the officer, in the court of chancery, who files all affidavits made use of in court.

Clerk *of the assize*, the person who writes all things judicially done by the justices of assize in their circuits.

Clerk *of the bails*, an officer in the court of king's bench, whose business it is to file all bail-pieces taken in that court, where he always attends.

Clerk *of the crown*, an officer, in the king's bench, who frames, reads, and records, all indictments against offenders, there arraigned or indicted of any public crime. He is likewise termed clerk of the crown-officer, in which capacity he exhibits informations by order of the court, for divers offences.

Clerk *of the crown*, in chancery, an officer whose business it is constantly to attend the lord-chancellor, in person or by deputy, to write and prepare for the great seal, special matters of state by commission, both ordinary and extraordinary, viz. commissions of lieutenancy, of justices of assize, oyer and terminer, gaol-delivery, and of the peace; all general pardons, granted either at the king's coronation, or in parliament: the writs of parliament, with the names of the knights, citizens, and burgesses, are also returned into his office. He also makes out special pardons, and writs of execution on bonds of statute-staple forfeited.

Clerk *of the declarations*, he that files all declarations after they are engrossed, in causes depending in the court of king's bench.

Clerk *of the deliveries*, an officer of the Tower, whose function is to take indentures for all stores and ammunition used from thence.

Clerk *of the errors*, in the court of common pleas, an officer who transcribes and certifies into the king's bench, the tenor of the record of the action on which the writ of error, made out by the cursitor, is brought there to be determined. In the king's bench, the clerk of the

errors transcribes and certifies the records of causes, by bill in that court, into the exchequer. And the business of the clerk of the errors in the exchequer, is to transcribe the records certified thither out of the king's bench, and to prepare them for judgment in the exchequer chamber.

Clerk *of the essoins*, in the court of common pleas, keeps the essoin-roll, or enters essoins: he also provides parchment, cuts it into rolls, marks the number of them, delivers out all the rolls to every officer, and receives them again when written.

Clerk *of the estreats*, an office in the exchequer, who every term receives the estreats out of the lord-treasurer's remembrancer's office, and writes them out, to be levied for the crown.

Clerk *of the hamper* or *hanaper*, an officer in chancery, whose business is to receive all money due to the king for the seals of charters, letters patent, commissions, and writs; also the fees due to the officers for enrolling and examining them.

Clerk *of the enrolments*, an officer of the court of common pleas, that enrols and exemplifies all fines and recoveries, and returns writs of entry.

Clerk *of the juries*, an officer of the common pleas, who makes out the writs, called habeas-corpus and distringas, for juries to appear either in that court, or at the assizes, after the panuels are returned upon the venire facias. He likewise enters into the rolls the awarding these writs, and makes all the continuances till verdict is given.

Clerk *controler of the king's household*, an officer of the king's court, authorized to allow or disallow the charges of pursuivants, messengers of the green cloth, &c. to inspect and control all defects of any of the inferior officers; and to sit in the counting-house with the lord-steward and other officers of the household, for regulating such matters.

Clerk *of the king's silver*, an officer of the common pleas, to whom every fine is brought, after it has passed the office of the custos brevium; and who enters the effect of writs of covenant, into a book kept for that purpose, according to which all the fines of that term are recorded in the rolls of the court.

Clerk *of the king's great wardrobe*, an officer who keeps an account of all things belonging to the wardrobe.

Clerk *of the market*, an officer of the king's house, to whom is given the charge of the king's measures and weights, the standards of those that ought to be used all over England.

Clerk *of the nichils*, or *nihils*, an officer of the exchequer, who makes a roll of all such sums as are nichilled by the sheriffs upon their estreats of green wax, and delivers them in to the remembrancer of the treasury, to have execution done upon them for the king.

Clerk *of the ordnance*, an officer that registers all orders concerning the king's ordnance in the Tower.

Clerk *of the outlawries*, an officer of the common pleas, and deputy to the attorney-general, for making out all writs of capias utlegatum after outlawry, to which there must be the king's attorney's name.

Clerk *of the paper-office*, an officer belonging to the king's bench, whose business is to make up the paper-books of special pleadings in that court.

Clerk *of the parliament-rolls*, an officer in the house of lords, and likewise in the house of commons, who records all transactions in parliament, and engrosseses them fairly in parchment rolls.

Clerk *of the peace*, an officer belonging to the sessions of the peace, whose business is to read indictments, enrol the proceedings, and draw the process; he likewise certifies into the king's-bench, transcripts of indictments, outlawries, attainders, and convictions, had before the justices of peace, within the time limited by statute, under a certain penalty. This office is in the gift of the custos rotulorum, and may be executed by deputy.

Clerk *of the pells*, an officer that belongs to the exchequer, whose business it is to enter every teller's bill into a parchment roll called pellis receptorum, and to make another roll of payments, called pellis exitunm.

Clerk *of the petty bag*, officers of the court of chancery, of which there are three, the master of the rolls being the chief: their business is to record the return of all inquisitions out of every shire, to make out patents of customers, gaugers, controlers, &c. liberates upon extents of statute-staple, congé-d'elires for bishops; summons of the nobility, clergy, and burgesses to parliament; and commissions directed to knights and others, of every shire, for assessing subsidies and taxes.

Clerk *of the pipe*, an officer of the exchequer, who having the accounts of all debts due to the king, delivered out of the remembrancer's office, charges them in a great roll, folded up like a pipe. He writes out warrants to sheriffs, to levy the said debts on the goods and chattels of the debtors; and if they have no goods, then he draws them down to the treasurer's remembrancer, to write estreats against their lands.

Clerk *of the pleas*, an officer of the exchequer, in whose office all the officers of the court, having special previlege, ought to sue, or be sued, in any action. In this office also actions at law may be prosecuted by other persons, but the plaintiff ought to be tenant or debtor to the king, or some way accountable to him. The under-clerks are attorneys in all suits.

Clerks *of the the privy-seal*, four officers that attend the lord privy seal, for writing and making out all things that are sent by warrant from the signet to the privy seal, and to be passed the great seal; and likewise to make out privy seals, upon special occasions of his majesty's affairs, as for loan of money, or the like.

Clerk *of the rolls*, an officer of the chancery, whose business is to make searches after, and copies of, deeds, offices, &c.

Clerk *of the rules*, an officer of the court of king's bench, who draws up and enters all the rules and orders made in court, and gives rules of course in divers writs.

Clerk *of the sewers*, an officer who writes and records the proceedings of the commissioners of the sewers.

Clerk *of the signet*, an officer continually attending upon his majesty's principal secretary, who has the custody of the privy signet, as well for sealing the king's private letters, as those grants which pass the king's hand by bill signed. There are four of these officers, who have their diet at the secretary's table.

Clerks, *six*, officers in chancery, next in degree below the twelve masters; whose business is to enrol commissions, pardons, patents, warrants, &c. which pass the great seal: they were anciently clerici, and forfeited

their places if they married. They are also attorneys for parties in suits depending in the court of chancery.

Clerk *of the supersedeas*, an officer of the common pleas, who makes out writs of supersedeas, forbidding the sheriff to return the exigent upon a defendant's appearing thereto on an outlawry.

Clerk *of the treasury*, an officer belonging to the court of common pleas, who has the charge of keeping the records of the court, makes out all records of nisi prius, and likewise all exemplifications of records being in the treasury. He has the fees due for all searches; and has under him an underkeeper, who always keeps one key of the treasury-door.

Clerk *of the warrants*, an officer of the common pleas, whose business is to enter all warrants of attorney for plaintiffs and defendants in suit; and to enrol deeds of bargain and sale, that are acknowledged in court, or before a judge. His office is likewise to estreat into the exchequer all issues, fines, estreats, and amercements, which grow due to the crown in that court.

CLERODENDRUM, a genus of the didynamia angiospermia class of plants, the flower of which consists of only one petal, with a slender and long tube; its upper lip is concave, erect, obtuse, and divided into two segments; and the under lip, being of the length of the upper, is divided into three reflex and obtuse segments: the fruit is a roundish drupe; and the seed is roundish and single. There are eight species, natives of the East Indies.

CLETHRA, a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 18th order, bicornes. The calyx is quinquepartite; the petals five; the stigma trifid; the capsule triocular and three-valved. There are four species, of which the most remarkable is,

Clethra alnifolia, a native of Virginia and Carolina, where it grows in moist places, and near the sides of rivulets, rising near eight or ten feet high. The leaves are shaped like those of the alder, but longer; the flowers are produced in close spikes at the extremities of the branches: they are white. This plant bears the open air in Britain, and is one of the most beautiful flowering shrubs. Its season is commonly about the beginning of July; and, if not very hot, there will be part of the spikes in beauty till the middle of September. It thrives best in moist land, and requires a sheltered situation, where it may be defended from strong winds, which frequently break off the branches where they are too much exposed to their violence. It is propagated by layers, but they are generally two years before they take root.

CLEW *of a sail*, in naval affairs, is the lower corner of it, to which are made fast the sheets and tacks: a square sail has no clew.

Clew-garnet, a rope made fast to the clew of the sail, and running thence to the block, seized to the middle of the main and fore yard; which, in furling, hales up the clew of the sail close to the middle of the yard.

Clew-line, the same to the top-sails, top-gallant-sails, and sprit-sails, that the clew-garnet is to the main-sail and fore-sail, and of the same use.

CLIBADIUM, a genus of the monoecia pentandria class and order. The male calyx is imbricate; corolla of the disk five-cleft. The female, common calyx the same; corolla of the ray female three or four; seed an umbilicate drupe. There is one species, a native of Surinam.

CLIFFORTIA, a genus of the polyandria order, in the dioecia class of plants: and in the natural method ranking under the 38th order, tricoccæ. The male calyx is triphyllous, no corolla; the stamina near 30 in number; the female calyx triphyllous, superior to the receptacle of the fruit; no corolla; two styles, with a bilocular capsule, and a single seed. There are 19 species, all natives of Africa; so require to be kept in a greenhouse when cultivated in this country. Their flowers make no great appearance; but the plants themselves are very ornamental ever-greens. They grow to the height of four or five feet; and are propagated by cuttings, which must be young shoots of five or six inches long. If planted in pots in spring or summer, and plunged in a hotbed, they will readily take root. They must be watered plentifully in summer, but very sparingly in winter.

CLIMACTERIC, among physicians and natural historians, a critical year in a person's life, in which he is supposed to stand in great danger of death. According to some, every seventh year is a climacteric; but others allow only those years produced by multiplying seven by the odd numbers, 3, 5, 7, and 9, to be climacterical. These years, they say, bring with them some remarkable change with respect to health, life, or fortune: the grand climacteric is the sixty-third year; but some, making two, add to this the eighty-first: the other remarkable climacterics are the seventh, twenty-first, thirty-fifth, forty-ninth, and fifty-sixth. The credit of climacteric years can only be supported by the doctrine of numbers introduced by Pythagoras, and is probably nothing but superstitious nonsense.

CLIMATES, in geography, spaces upon the surface of the terrestial globe, contained between two parallels, so far distant from each other, that the longest day on one parallel differs half an hour from the longest day on the other. See Geography.

CLINCH, in the sea-language, that part of a cable which is bent about the ring of the anchor, and then seized, or made fast.

CLINCHING, in the sea-language, a kind of slight caulking used at sea, in a prospect of foul weather, about the ports: it consists in driving a little oakum into their seams, to prevent the water's coming in at them.

CLINIC medicine, particularly used for the method of visiting and treating sick persons in bed, and the more exact discovery of all the symptoms of their disease.

CLINOPODIUM, field-basil, a genus of the gymnospermia order, in the didynamia class of plants; and the natural method ranking under the 41st order, asperifoliæ. The involucrum consists of many small bristles under the verticillus or whorl of flowers. There are five species, all herbaceous plants growing from one to two feet high. They are remarkable only for their strong odour, being somewhat between marjoram and basil.

CLIO, in zoology, a genus of insects belonging to the vermes mollusca. The body is oblong and fitted for swimming: it has two membranaceous wings placed opposite to each other. There are three species, princi-

pally distinguished by the shape of the vagina, and all natives of the ocean. See Plate XXXIII. Nat. Hist. fig. 118.

CLITORIA, a genus of the decandria order in the diadelphia class of plants; and in the natural method ranking under the 32d order, papilionaceæ. The corolla is supine, or turned down-side up; with the vexillum or flag-petal very large, patent, and almost covering the alæ or wing-petals. There are five species, all herbaceous perennials; or annuals, of the kidney-bean kind, growing naturally in both the Indies. The stalk is climbing, slender, and of the height of a man. The leaves are winged. The flowers, which are elegant, stand singly, each on its proper footstalk. They are very large, and generally of a deep blue, but sometimes of a white colour. From the fruit of this plant is distilled an eye-water.

CLOACA, in Roman antiquity, the common sewer, by which the filth of the city of Rome was carried away. It was built with great stones, in the form of an arch, so well fastened and cemented together, that the continual running of water and filth had not damaged it in the space of 700 years. There were many sinks in the city, which all fell into this common sewer; and the officers appointed to take care of this work, and to see it repaired, were called curatores cloacarum urbis.

CLOATHED, in the sea-language. A mast is said to be cloathed, when the sail is so long as to reach down to the gratings of the hatches, so that no wind can blow below the sail.

CLOCK, a kind of movement or machine, serving to measure and strike time.

The usual chronometers are watches and clocks: the former are such as show the parts of time; the latter, such as publish it by striking: though the name *watch* is commonly appropriated to pocket-clocks; and that of *clock* to larger machines, whether they strike or no.

Clocks, *invention of.* The invention of clocks with wheels is ascribed to Pacificus, archdeacon of Verona, who lived in the time of Lothair son of Lewis the Debonnair, on the credit of an epitaph quoted by Ughilli, and borrowed by him from Panvinius. They were at first called *nocturnal dials*, to distinguish them from sun-dials, which showed the hour by the sun's shadow. Others ascribe the invention to Boethius, about A. D. 510. Mr. Derham makes clock-work of a much older standing; and ranks Archimedes's sphere mentioned by Claudian, and that of Posidonius mentioned by Cicero, among the machines of this kind: not that either their form or use was the same with those of ours, but that they had their motion from some hidden weights or springs, with wheels, or pullies, or some such clock-work principle. But be this as it may, it is certain the art of making clocks, such as are now used, was either first invented, or at least revived, not more than 200 years ago. The clepsydræ, or water-clocks, and sun-dials, have a much better claim to antiquity. The French annals mention one of the former kind sent by Aaron, kalif of Persia, to Charlemagne, about A. D. 807, which seemed to bear some resemblance to the modern clocks. It was of brass, and showed the hours by 12 little balls of the same metal which fell at the end of each hour, and in falling struck a bell and made it sound. There were also figures of 12 cavaliers which at the end of each hour came forth at certain apertures or windows in the side of the clock, and shut them again, &c. The invention of pendulum clocks is owing to the happy industry of the century before last: the honour of it is disputed by Huygens and Galileo. The former, who has written a volume on the subject, declares it was first put in practice in 1657, and the description thereof printed in 1658. Becher, *de Nova Temporis dimetiendi Theoria*, A. D. 1680, contends for Galileo: and relates, though at second-hand, the whole history of the invention; adding that one Tresler, clock-maker to the then father of the grand duke of Tuscany, made the first pendulum clock at Florence, by direction of Galileo Galilei; a pattern of which was brought into Holland. The Academy del Cimento says expressly, that the application of the pendulum to the movement of a clock was first proposed by Galileo, and first put in practice by his son Vincenzo Galilei, in 1649. Be the inventor who may, it is certain the invention never flourished till it came into Huygens's hands, who insists, that if ever Galileo thought of such a thing, he never brought it to any degree of perfection. The first pendulum clock made in England was in 1662, by Mr. Fromantil, a Dutchman. Before the invention of the pendulum a balance was used resembling the fly of a jack.

In Plate XXXII. fig. 1 is the profile of a clock: P is a weight that is suspended by a rope that winds about the cylinder or barrel C, which is fixed upon the axis *aa;* the pivots *bb* go into holes made in plates TS, TS, in which they turn freely. These plates are made of brass or iron, and are connected by 4 *pillars* ZZ; and the whole together is called the *frame*. The weight P, if not restrained, would necessarily turn the barrel C with an uniform accelerated motion, in the same manner as if the weight was falling freely from a height. But the barrel is furnished with a ratchet wheel KK, fig. the right side of whose teeth strikes against the click, which is fixed with a screw to the wheel D, so that the action of the weight is communicated to the wheel D, the teeth of which act upon the teeth of the small wheel *d* which turns upon the pivots *cc*. The communication or action of one wheel with another is called the *pitching;* a small wheel like *d* is called a *pinion*, and its teeth are leaves of the pinion. Several things are requisite to form a good pitching, the advantages of which are obvious in all machinery where teeth and pinions are employed. The teeth and pinion leaves should be of a proper shape, and perfectly equal among themselves; the size also of the pinion should be of a just proportion to the wheel acting into it; and its place must be at a certain distance from the wheel, beyond or within which it will make a bad pitching. The wheel EE is fixed upon the axis of the pinion *d;* and the motion communicated to the wheel DD by the weight is transmitted to the pinion *d*, consequently to the wheel EE, as likewise to the pinion *e* and wheel FF, which moves the pinion upon the axis of which the crown or balance wheel G H is fixed. The pivots of the pinion *f* play in holes of the plates L, M, which are fixed horizontally to the plates TS. The motion begun by the weight is transported from the wheel G H to the plates I K, and by means of the fork X U rivetted on the palettes, communicates motion to the pendulum A B, which is suspended upon the hook A. The pendulum A B describes, on the point A, an arc of a circle alternately go-

ing and returning. If then the pendulum is once put in motion by a push of the hand, the weight of the pendulum at B will make it return upon itself, and it will continue to go alternately backward and forward till the resistance of the air upon the pendulum, and the friction at the point of suspension at A, destroys the original impressed force. But at every vibration of the pendulum, the teeth of the balance wheel, G H, act so upon the palettes I K (the pivots upon the axis of these palettes play in two holes of the potence *s t*), that after one tooth H has communicated motion to the palette K, that tooth escapes; then the opposite tooth G acts upon the palette I, and escapes in the same manner; and thus each tooth of the wheel escapes the palettes I K, after having communicated their motion to the palettes in such a manner that the pendulum, instead of being stopped, continues to move. The wheel E E revolves in an hour; the pivot *c* of this wheel passes through the plate, and is continued to *r;* upon the pivot is a wheel N N with a long socket fastened in the centre: upon the extremity of this socket *r*, the minute-hand is fixed. The wheel N N acts upon the wheel O; the pinion of which *p* acts upon the wheel *q q*, fixed upon a socket, which turns along with the wheel N. This wheel *q q* makes its revolution in 12 hours, upon the socket of which the hour hand is fixed. Thus it is plain, 1. That the weight P turns all the wheels, and at the same time continues the motion of the pendulum. 2. That the quickness of the motion of the wheels is determined by that of the pendulum. 3. That the wheels point out the parts of time divided by the uniform motion of the pendulum. When the cord upon which the weight is suspended is entirely run down from off the barrel, it is wound up again by a key, which goes on the square end of the arbor at Q, by turning it in a contrary direction to that in which the weight descends. For this purpose, the inclined side of the teeth of the wheel R, fig. 2, removes the click C, so that the ratchet-wheel R turns while the wheel D is at rest; but as soon as the cord is wound up, the click falls in between the teeth of the wheel D, and the right side fo the teeth again acts upon the end of the click, which obliges the wheel D to turn along with the barrel; and the spring A keeps the click between the teeth of the ratchet-wheel R.

To explain how time is measured by the motion of the pendulum; and how the wheel E, upon the axis of which the minute-hand is fixed, makes but one precise revolution in an hour; we must observe, that the vibrations of a pendulum are performed in a shorter or longer time in proportion to the length of the pendulum itself. A pendulum of 3 feet 8½ French lines in length, makes 3600 vibrations in an hour: *i. e.* each vibration is performed in a second of time, and for that reason it is called a *second pendulum*. But a pendulum of 9 inches 2¼ French lines makes 7200 vibrations in an hour, or two vibrations in a second of time, and is called *a half-second pendulum*.

Hence, in constructing a wheel whose revolution must be performed in a given time, the time of the vibrations of the pendulum which regulates its motion, must be considered. Supposing, then, that the pendulum A B makes 7200 vibrations in an hour, let us consider how the wheel E shall take up an hour in making one revolution. This entirely depends on the number of teeth in the wheels and pinions. If the balance wheel consists of 30 teeth, it will turn once in the time that the pendulum makes 60 vibrations: for at every turn of the wheel, the same tooth acts once on the palette I, and once on the palette K, which occasions two separate vibrations in the pendulum; and the wheel having 30 teeth, it occasions twice 30, or 60 vibrations. Consequently, this wheel must perform 120 revolutions in an hour; because 60 vibrations, which it occasions at every revolution, are contained 120 times in 7200, the number of vibrations performed by the pendulum in an hour. To determine the number of teeth for the wheels E E, and their pinions *e*, *f*, it must be remarked, that one revolution of the wheel E must turn the pinion *e* as many times, as the number of teeth in the pinion is contained in the number of teeth in the wheel. Thus, if the wheel E contains 72 teeth, and the pinion *e*, 6, the pinion will make 12 revolutions in the time that the wheel makes 1; for each tooth of the wheel drives forward the tooth of the pinion; and when the six teeth of the pinion are moved, a complete revolution is performed; but the wheel E has by that time only advanced 6 teeth, and has still 66 to advance before its revolution is completed, which will occasion 11 more revolutions of the pinion. For the same reason, the wheel F having 60 teeth, and the pinion *f* 6, the pinion will make 10 revolutions while the wheel performs one. Now, the wheel F, being turned by the pinion *e*, makes 12 revolutions for one of the wheel E: and the pinion *f* makes 10 revolutions for one of the wheel F; consequently the pinion *f* performs 10 times 12 or 120 revolutions in the time the wheel E performs one. But the wheel G, which is turned by the pinion *f*, occasions 60 vibrations in the pendulum each time it turns round; consequently the wheel G occasions 60 times 120 or 7200 vibrations of the pendulum while the wheel E performs one revolution; but 7200 is the number of vibrations made by the pendulum in an hour; and consequently the wheel E performs but one revolution in an hour, and so of the rest. From this reasoning, it is easy to discover how a clock may be made to go for any length of time without being wound up: 1. By increasing the number of teeth in the wheels; 2. By diminishing the number of teeth in the pinions; 3. By increasing the length of the cord that suspends the weight; 4. By increasing the length of the pendulum; and, 5. By adding to the number of wheels and pinions. But, in proportion as the time is augmented, if the weight continues the same, the force which it communicates to the last wheel, G H, will be diminished. It only remains to take notice of the number of teeth in the wheels which turn the hour and minute hands. The wheel E performs one revolution in an hour; the wheel N N, which is turned by the axis of the wheel E, must likewise make one revolution in the same time; and the minute-hand is fixed to the socket of this wheel. The wheel N has 30 teeth, and acts upon the wheel O, which has likewise 30 teeth, and the same diameter; consequently the wheel O takes one hour to a revolution: now the wheel O carries the pinion *p*, which has six teeth, and which acts upon the wheel *qq* of 72 teeth; consequently the pinion *p* makes 12 revolutions, while the wheel *qq* makes one; and of course the wheel *qq* takes 12 hours to one revolution, and upon the socket of this wheel the hour-hand is fixed. All that has been said here con-

cerning the revolutions of the wheels, &c. of clocks, is equally applicable to the general movements of watches.

Dr. Franklin contrived a clock to show the hours, minutes, and seconds with only three wheels and two pinions in the whole movement. The dial-plate, fig. 3. has the hours engraved upon it in spiral spaces along two diameters of a circle containing four times 60 minutes. The index A goes round in four hours, and counts the minutes from any hour which it has passed to the next following hour. The time, therefore, in the position of the index shown in the figure, is either 30 minutes past XII, IV, or VIII; and so in every other quarter of the circle it points to the number of minutes after the hours which the index last left in its motion. The small hand B, in the arch at top, goes round once in a minute, and shows the seconds. The wheel-work of this clock may be seen in fig. 4. A is the first or great wheel containing 160 teeth, and going round in four hours with the index A in fig. 3 let down by a hole on its axis. The wheel turns a pinion of 10 leaves, which therefore goes round in a quarter of an hour. On the axis of this pinion is the wheel C of 120 teeth; which goes round in the same time, and turns a pinion D of 8 leaves round in a minute, with the second-hand B of fig. 3 fixed on its axis, and also the common wheel E of 30 teeth for moving a pendulum (by palettes) that vibrates seconds, as in a common clock. This clock is wound up by a cord going over a pulley on the axis of the great wheel, like a common thirty-hours clock. Many of these admirably simple machines have been constructed, which measure time exceedingly well. It is subject, however, to the inconvenience of requiring frequent winding by drawing up the weight, and likewise to some uncertainty as to the particular hour shown by the index A. Mr. Ferguson has proposed to remedy these inconveniences by the following construction: In the dial-plate of his clock, fig. 5, there is an opening, *a b c d*, below the centre; through which appears part of a flat plate: on this the 12 hours, with their divisions into quarters, are engraved. This plate turns round in 12 hours: and the index A points out the true hour, &c. B is the minute-hand, which goes round the large circle of 60 minutes whilst the plate *a b c d* shifts its place one hour under the fixed index A. There is another opening, *e f g h*, through which the seconds are seen on a flat moveable ring at the extremity of a fleur-de-lis engraved on the dial-plate. A in fig. 6 is the great wheel of this clock, containing 120 teeth, and turning round in 12 hours. The axis of this wheel bears the plate of hours, which may be moved by a pin passing through small holes drilled in the plate, without affecting the wheel-work. The great wheel A turns a pinion B of 10 leaves round in an hour, and carries the minute-hand B on its axis round the dial-plate in the same time. On this axis is a wheel C of 120 teeth, turning round a pinion D of 6 leaves in three minutes: on the axis of which there is a wheel E of 90 teeth, that keeps a pendulum in motion, vibrating seconds by palettes, as in a common clock, when the pendulum-wheel has only 30 teeth, and goes round in a minute. In order to show the seconds by this clock, a thin plate must be divided into 3 times 60, or 180 equal parts, and numbered 10, 20, 30, 40, 50, 60, three times successively; and fixed on the same axis with the wheel of 90 teeth, so as to turn round near the back of dial-plate: and these divisions will show the seconds through the opening *e f g h*, fig. 5. This clock will go a week without winding, and always show the precise hour; but this clock, as Mr. Ferguson candidly acknowledges, has two disadvantages of which Dr. Franklin's clock is free. When the minute-hand B is adjusted, the hour-plate must also be set right by means of a pin: and the smallness of the teeth in the pendulum wheel will cause the pendulum ball to discribe but small arcs in its vibrations: and therefore the momentum of the ball will be less, and the times of the vibrations will be more affected by any unequal impulse of the pendulum wheel on the palettes. Besides, the weight of the flat ring on which the seconds are engraved will load the pivots of the axis of the pendulum wheel with a great deal of friction, which ought by all possible means to be avoided. To remedy this inconvenience, the second-plate might be omitted. A clock similar to Dr. Franklin's was made in Lincolnshire many years ago.

Thus far refers to what is usually called clock-work; but watches are so far on a different construction that they are set in motion by a spring. The manner that a weight acts upon the cylinder, about which the line or cord to which it hangs is wound, is easy to be understood by all; but the action of the spring coiled up within the cylindric barrel, or box of a clock or watch, is somewhat more nice and mysterious; and the manner how it acts upon the fusee always with an equal force, by means of the chain and the proper figure of the fusee for that purpose is next to be explained.

The chain being fixed at one end of the fusee, and at the other to the barrel; when the machine is winding up, the fusee is turned round, and of course the barrel; on the inside of which is fixed one end of the spring, the other end being fixed to an immoveable axis in the centre. As the barrel moves round, it coils the spring several times about the axis, thereby increasing its elastic force to a proper degree: all this while the chain is drawn off the barrel upon the fusee; and then, when the instrument is wound up, the spring, by its elastic force endeavouring constantly to unbend itself, acts upon the barrel, by carrying it round, by which the chain is drawn off from the fusee, and thus turns the fusee, and consequently the whole machinery. Now as the spring unbends itself by degrees, its elastic force, by which it affects the fusee, will gradually decrease; and therefore, unless there was some mechanical contrivance in the figure of the superficies of the fusee, to cause, that, as the spring grows weak, the chain shall be removed farther from the centre of the fusee, so that what is lost in the spring's elasticity is gained in the length of the lever: was it not for this contrivance, the spring's force would always be unequal upon the fusee, and thus would turn the fusee and consequently the whole machinery, unequally. All this is remedied by the conical figure of the fusee. The fusee being acted upon, or put in motion, by an uniform force, the great wheel, which is fixed to it, is put into motion, and that drives the pinion of the centre-wheel, which centre-wheel drives the pinion of the third wheel, and this drives the pinion of the contrate wheel, and this the pinion of the balance-wheel, which plies the two pa-

lettes on the axis of the balance, and keeps the balance in motion.

The balance in a watch is instead of the pendulum in a clock, both serving to govern the motion of the whole machinery. To this balance is fixed a small steel spiral spring, which regulates its motions, and makes it equable: whence it has its name of regulator.

When the watch is wound up, the chain from the spring exerts a force upon the fusee, which gives motion to all the parts of the machine, in the following manner; as will be easy to understand, when the number of teeth in each wheel, and leaves in the pinions which they drive, are specified, and these in modern thirty-hour watches are as follows:

	Teeth.	Leaves.
Great wheel	48	12
Centre-wheel	54	6
Third wheel	48	6
Contrate-wheel	48	6
Balance-wheel	15	2 palettes.

Hence it is easy to conceive how often any one wheel moves round in the time of one revolution of that which drives it.

Thus the great wheel on the fusee, having 48 teeth, and driving the centre-wheel by a pinion of 12, must cause the centre-wheel to move round four times in one turn of the fusee, and so for all the rest, as follows:

12) 48 (4 = turns of the centre
6) 54 (9 = turns of the third
6) 48 (8 = turns of the contrate
6) 48 (8 = turns of the balance
} wheel.

Whence it follows, that the turns of each of these wheels respectively, in one turn of the fusee, will be had by multiplying those several quotients together successively, as follows:

	1	Turns of the	fusee-wheel.
$4 \times 1 =$	4		centre-wheel.
$9 \times 4 \times 1 =$	36		third-wheel.
$8 \times 9 \times 4 \times 1 =$	288		contrate-wheel.
$8 \times 8 \times 9 \times 4 \times 1 =$	2304		balance-wheel.

But all that has been hitherto said shows only the minutes of an hour, and seconds or quarter-seconds of a minute; for nothing has been yet mentioned relating to the mechanism for showing the hour of the day. This part of the work lies concealed from sight, between the upper plate of the watch-frame and the dial-plate. In this work, A B C (Plate XXXII. fig. 7.) is the uppermost side of the frame-plate, as it appears when detached from the dial-plate: the middle of this plate is perforated with a hole, receiving that end of the arbor of the centre-wheel which carries the minute-hand; near the plate is fixed a pinion *a b* of ten teeth: this is called the pinion of report; it drives a wheel *c d* of forty teeth; this wheel *c d* carries a pinion *e f* of twelve teeth; and this drives a wheel *g h* with thirty-six teeth.

As in the body of the watch the wheels every where divide the pinions, here, on the contrary, the pinions divide the wheels, and by that means decrease the motion, which is here necessary; for the hour hand, which is carried on a socket fixed on the wheel *g h*, is required to move but once round, while the pinion *a b* moves twelve times round. To this end the motion of the wheel *c d* is $\frac{1}{4}$ of the pinion *ab:* again, while the wheel *c d*, or the pinion *e f*, goes once round, it turns the wheel *g h* but $\frac{1}{3}$ part round; consequently the motion of *gh* is but $\frac{1}{3}$ of $\frac{1}{4}$ of the motion of *ab;* but $\frac{1}{3}$ of $\frac{1}{4} = \frac{1}{12}$, that is, the hour-wheel *gh* moves once round in the time that the pinion of report, on the arbor of the centre or minute-wheel, makes twelve motions, as required.

Clock-work, properly so called, is that part of the movement which strikes the hours, &c. on a bell; in contradistinction to that part of the movement of a clock or watch which is designed to measure and exhibit the time on a dial-plate, and which is termed watch-work. The wheels composing the clock part are: the great or first wheel E (see Plate XXXII. fig. 8), which is moved by the weight or spring at the barrel D: in sixteen or thirty-hour clocks, this has usually pins, and is called the pin-wheel; in eight-day pieces the second wheel L is commonly the pin-wheel, or striking wheel, which is moved by the former. Next the striking wheel is the detent wheel, or hoop wheel *m*, having a hoop almost round it, wherein is a vacancy at which the clock locks. The next is the third or fourth wheel, according to its distance from the first, called the warning wheel, *n*. To these must be added the pinion of report, *z*, which drives round the locking wheel, called also the count wheel; ordinarily with eleven notches in it, unequally distant, to make the clock strike the hours. Besides the wheels, to the clock part belong the rash or ratch; a kind of wheel with twelve large fangs, running concentrical to the dial wheel, and serving to lift up the detents every hour, and make the clock strike: the detents or stops, which being lifted up and let fall, lock and unlock the clock in striking; the hammer, as S, which strikes the bell R; the hammer-tails, as T, by which the striking pins draw back the hammers; latches, whereby the work is lifted up and unlocked; and lifting pieces, as P, which lift up and unlock the detent O. The method of calculating the numbers of a piece of clock-work has something in it very entertaining, and at the same time easy and useful. We therefore shall here give the rules: 1. Regard here needs only be had to the count wheel, striking wheel, and detent wheel, which move round in this proportion: the count wheel commonly goes round once in twelve or twenty-four hours; the detents wheel moves round every stroke the clock strikes, or sometimes but once in two strokes: wherefore it follows, that, 2. As many pins as are in the pin wheel, so many turns has the detent wheel in one turn of the pin wheel; or, which is the same, the pins of the pin wheel are the quotients of that wheel divided by the pinion of the detent wheel. But if the detent wheel move but once round in two strokes of the clock, then the said quotient is but half the number of pins. 3. As many turns of the pin wheel as are required to perform the strokes of 12 hours (which are 78), so many turns must the pinion of report have to turn round the count wheel once: or thus, the quotient of 78, divided by the number of striking pins, shall be the quotient for the pinion of report and the count wheel; and this is in case the pinion of report be fixed to the arbor of the pin wheel, which is commonly done. An example will make all plain: the

locking wheel being 48, the pinion of report 8, the pin wheel 78, the striking pins are 13, and so of the rest. Note also, that 78 divided by 13 gives 6, the quotient of the pinion of report. As for the warning wheel and fly wheel, it matters little what numbers they have; their use being only to bridle the rapidity of the motion of the other wheels.

8) 48 (6.
6) 78 (13.
6) 60 (10.
6) 48 (8.

The watch part of a clock or watch is that part of the movement which is designed to measure and exhibit the time on a dial-plate; in contradistinction to that part which contributes to the striking of the hour, &c. The several members of the watch parts are, 1. The balance, consisting of the rim, which is its circular part; and the verge, which is its spindle; to which belong two palettes, or leaves, that play in the teeth of the crown wheel. 2. The potence, or pottance, which is the strong stud in pocket-watches, whereon the lower pivot of the verge plays, and in the middle of which one pivot of the balance wheel plays; the bottom of the pottance is called the foot, the middle part the nose, and the upper part the shoulder. 3. The cock, which is the piece covering the balance. 4. The regulator, or pendulum spring, which is the small spring, in watches, underneath the balance. 5. The pendulum (see Plate XXXII. fig. 8), whose parts are, the verge, palettes 5,5, cocks, the rod, the fork, the flat, the bob or great hall, and the corrector or regulator, being a contrivance for bringing the pendulum to its nice vibrations. 6. The wheels, which are the crown wheel F, in pocket pieces, and swing wheel in pendulums; serving to drive the balance or pendulum. 7. The contrate wheel E, which is that next the crown wheel, &c. and whose teeth and hoop lie contrary to those of other wheels; whence the name. 8. The great, or first wheel C; which is that which the fusee immediately drives, by means of the chain or string of the spring box or barrel D; after which are the second wheel, third wheel, &c. Lastly, between the frame and dial-plate is the pinion of report, which is that fixed on the arbor of the great wheel; and serves to drive the dial wheel, as that serves to carry the hand. The method of calculation is easily understood: for suppose the great wheel E goes round once in 12 hours; then if it is a royal pendulum clock, swinging seconds, we have $60 \times 60 \times 12 = 43200$ seconds or beats in one turn of the great wheel: but because there are sixty beats or seconds in one minute, and the seconds are shown by an index on the end of the arbor of the swing wheel, which in those clocks is an horizontal position; therefore it is necessary that the swing wheel should have 60 teeth; whence $\frac{43200}{60} = 720$, the number to be broken into quotients for finding the number of teeth for the other wheels and pinions.

In the year 1803 the Society for the Encouragement of Arts, &c. presented to Mr. John Prior, of Nessfield, Yorkshire, a reward of thirty guineas, on account of his contrivance for the striking part of an eight-day clock. It consists of a wheel and fly, with six turns of a spiral line, cut upon the wheel for the purpose of counting the hours. The pins below this spiral elevate the hammer, and those above are for the use of the detent. This single wheel serves the purpose of count-wheel, pin-wheel, detent-wheel, and the fly-wheel, and has six revolutions in striking the twelve hours. If we suppose a train of wheels and pinions used in other striking parts to be made without error, and that the wheels and pinions would turn each other without shake or play; then allowing the above supposition to be true (though every mechanic knows it is not), Mr. Prior's striking part would be found six times superior to others, in striking the hours 1, 2, 5, 7, 10, 11; twelve times superior in striking 4, 6, 8; and 18 times, in striking 3, 9, and 12. In striking 2, the inventor purposely made an imperfection equal to the space of three teeth of the wheel; and in striking 3, an imperfection of nine or ten teeth; and yet both these hours are struck perfectly correct.

Clocks, *table and rules for regulating.* By the following table, clocks and watches may be so regulated as to measure true equal time.

D.	H.	M.	S.	D.	H.	M.	S.
1	0	3	56	16	1	2	54
2	0	7	52	17	1	6	50
3	0	11	48	18	1	10	46
4	0	15	44	19	1	14	42
5	0	19	39	20	1	18	38
6	0	23	35	21	1	22	34
7	0	27	31	22	1	26	30
8	0	31	27	23	1	30	26
9	0	35	23	24	1	34	22
10	0	39	19	25	1	38	17
11	0	43	15	26	1	43	13
12	0	47	11	27	1	46	9
13	0	51	7	28	1	50	5
14	0	55	3	29	1	54	1
15	0	58	58	30	1	57	57

The stars make 366 revolutions from any point of the compass to the same point again in 365 days and one minute; and therefore they gain a 365th of a revolution every 24 hours of mean solar time, near enough for regulating any clock or watch. This acceleration is at the rate of 3 min. 55 sec. 53 thirds, 59 fourths, in 24 hours; or, in the nearest round numbers, 3 min. 56 sec. by which quantity of time every star comes round sooner than it did on the day before. Therefore if you mark the precise moment shown by a clock or watch when any star vanishes behind a chimney, or any other object, as seen through a small hole in a thin plate of metal, fixed in a window-shutter; and do this for several nights successively (as suppose twenty); if at the end of that time the star vanishes as much sooner than it did the first night, by the clock, as answers to the time denoted in the table for so many days, the clock goes true, otherwise not. If the difference between the clock and the star be less than the table shows, the clock goes too fast; if greater, it goes too slow, and must be regulated accordingly, by letting down or raising the ball of the pendulum, by little and little, by turning the screw-nut under the ball, till you find it keeps true equal time. Thus, supposing the star should disappear behind a chimney any night when it is 12 by the clock, and that on the 20th night afterward the same star should disappear when the time is 41 min. 22 sec. past 10 by the clock, which being subtracted from 12 hours, 0 min. 0 sec. leaves remaining 1 hour 18 min. 38

sec. for the time the star is then faster than the clock; look in the table, and against 20, in the left hand column, you will find the acceleration of the star to be 1 hour, 18 min. 38 sec. agreeing exactly with what the difference ought to be between the clock and star; which shows that the clock measures true equal time, and agrees with the mean solar time, as it ought to do.

CLOCK-WORK, *extraordinary pieces of.* Amongst the modern clocks, those at Strasburg and Lyons are very eminent for the richness of their furniture, and the variety of their motions and figures. In the former, a cock claps his wings, and proclaims the hour; and the angel opens a door, and salutes the Virgin, and the Holy Spirit descends on her, &c. In the latter, two horsemen encounter, and beat the hour on each other; a door opens, and there appear on the theatre the Virgin, with Jesus Christ in her arms; the magi, with their retinue, marching in order, and presenting their gifts, two trumpeters sounding all the while to proclaim the procession. These, however, are excelled by two which were lately made by English artists, and sent as a present from the East India company to the emperor of China. These clocks are in the form of chariots, in which are placed, in a fine attitude, a lady, leaning her right hand upon a part of the chariot; under which is a clock of curious workmanship, little larger than a shilling, that strikes and repeats, and goes eight days. Upon her finger sits a bird finely modelled, and set with diamonds and rubies, with its wings expanded in a flying posture, and actually flutters for a considerable time on touching a diamond button below it; the body of the bird (which contains part of the wheels that in a manner give life to it) is not the bigness of the 16th part of an inch. The lady holds in her left hand a gold tube, not much thicker than a large pin, on the top of which is a small round box, to which a circular ornament set with diamonds not larger than a sixpence is fixed, which goes round near three hours in a constant regular motion. Over the lady's head, supported by a small fluted pillar no bigger than a quill, are two umbrellas: under the largest of which a bell is fixed, at a considerable distance from the clock, and seeming to have no connection with it; but from which a communication is secretly conveyed to a hammer, that regularly strikes the hour, and repeats the same at pleasure by touching a diamond button fixed to the clock below. At the feet of the lady is a gold dog, before which, from the point of the chariot, are two birds, fixed on spiral springs; the wings and feathers of which are set with stones of various colours, and appear as if flying away with the chariot, which, from another secret motion, is contrived to run in a straight, circular, or any other direction. A boy that lays hold of the chariot behind seems also to push it forward. Above the umbrella are flowers and ornaments of precious stones, and it terminates with a flying dragon set in the same manner. The whole is of gold, most curiously executed, and embellished with rubies and pearls.

CLOCKS, *statutes respecting.* By stat. 9 and 10 W. III. cap. 28. § 2. no person shall export, or endeavour to export, out of this kingdom, any outward or inward box, case, or dial-plate, of gold, silver, brass, or other metal, for clock or watch, without the movement in or with every such box, &c. made up fit for use, with the maker's name engraved thereon; nor shall any person make up any clock or watch without putting his name and place of abode or freedom, and no other name or place, on every clock or watch, on penalty of forfeiting every such box, case, and dial-plate, clock and watch, not made up and engraved as aforesaid; and 20*l.*; one moiety to the king, the other to those that shall sue for the same. By stat. 17 Geo. III. cap. 108. an annual duty must be paid of 5*s.* for every clock or time-keeper, of 10*s.* for every gold watch, and 2*s.* 6*d.* for every silver or metal watch, by the respective proprietors; under the penalty of 10*l.* for neglecting to deliver lists of these articles, or double duty for omissions in such lists, and of 10*l.* more for not giving in a declaration respecting them within 14 days after receiving notice from the assessors. Duties on clocks let with houses are to be paid by the occupiers, but when these are empty, by the landlords. These duties do not extend to such householders as are not liable to the house and window tax, for one clock, or one silver or metal watch. Clocks not worth more than 20*s.* are also exempted, to occupiers of houses not exceeding ten windows. The royal family, foreign ambassadors, hospitals, churches, servants in husbandry, soldiers, marines, sailors, and licensed watchmakers, pawn-brokers, and dealers in clocks and watches, are also exempted. These last must pay 2*s.* 6*d.* annually for their licenses within London and Westminster, and 1*s.* elsewhere, under a penalty of 5*l.* This act has been since repealed.

CLOFF, that in which any goods are put for the convenience of carriage; as the bags of pepper or hops, the barrels of butter, soap, &c.

CLOSE, in heraldry. When any bird is drawn in a coat of arms with its wings close down about it, and in a standing posture, they blazon it by this word *close;* but if it is flying they call it volant.

CLOSE-FIGHTS, in the sea-language, such bulk-heads as are in a close fight put up fore and aft in ship, for the men to stand behind them secure, and fire upon the enemy; and if the ship is boarded, to secure and clear the decks.

CLOTH, in commerce, a manufacture made of wool wove on the loom.

The term is applicable also to other manufactures made of hemp, flax, &c. but in a more particular sense it implies the web or tissue of woollen threads interwoven; some whereof, called the warp, are extended in length from one end of the piece to the other: the rest, called the woof, disposed across the first, or breadthwise of the piece.

The best wool for the manufacturing of cloths are those of England and Spain, especially those of Lincolnshire and Segovia. To use those wools to the best advantage, they must be scoured, by putting them into a liquor somewhat more than lukewarm, composed of three parts fair water, and one of urine. After the wool has continued long enough in the liquor to soak, and dissolve the grease, it is drained and well washed in running water. When it feels dry, and has no smell but that of the sheep, is said to be duly scoured. After this it is hung to dry in the shade, the heat of the sun making it harsh and inflexible; when dry, it is beaten with rods upon hurdles of wood, or on cords, to cleanse it from dust and the grosser filth; the more it is thus beaten and cleansed, the softer it becomes, and the better for spinning. After beating, it must be well picked, to free

it from the rest of the filth that had escaped the rods. It is now in a proper condition to be oiled, and carded on large iron cards, placed slopewise. Olive-oil is esteemthe best for this purpose: one-fifth of which should be used for the wool intended for the woof, and a ninth for that designed for the warp. After the wool has been oiled, it is given to the spinners; who first card it on the knee, with small cards, and then spin it on the wheel; observing to make the thread of the warp smaller by one-third than that of the woof, and much compacter-twisted. The thread being thus spun, reeled, and made into skeins, that designed for the woof is wound on little tubes, pieces of paper, or rushes, so disposed as that they may be easily put into the eye of the shuttle. When warped, it is stiffened with size, the best of which is that made of shreds of parchment, and when dry, is given to the weavers; who mount it on the loom.

The warp being thus mounted, the weavers, who are two to each loom, one on each side, tread alternately on the treadle, first on the right step, and then on the left, which raises and lowers the threads of the warp equally; between which they throw transversely the shuttle from the one to the other: and every time that the shuttle is thus thrown, and a thread of the woof inserted within the warp, they strike it conjunctly with the same frame, to which is fastened the comb or reed between whose teeth the threads of the warp are passed, repeating the stroke as often as is necessary. The weavers having continued their work till the whole warp is filled with the woof, the cloth is finished; it is then taken off the loom by unrolling it from the beam whereon it had been rolled in proportion as it was woven; and now given to be cleansed of the knots, ends of threads, straws, and other filth, which is done with iron nippers.

In this condition it is carried to the fullery, to be scoured with urine; or a kind of potter's clay, well steeped in water, put along with the cloth in the trough wherein it is fulled. The cloth, being again cleared from the earth or urine, is returned to the former hands to have the lesser filth, small straws, &c. taken off as before: then it is returned to the fuller to be beaten and fulled with hot water, wherein a suitable quantity of soap has been dissolved; after fulling it is taken out to be smoothed, or pulled by the lists lengthwise, to take out the wrinkles, crevices, &c. The smoothing is repeated every two hours till the fulling is finished, and the cloth brought to its proper breadth: after which it is washed in clear water, to purge it of the soap, and given wet to the carders to raise the hair or nap on the right side with the thistle or weed. After this preparation the cloth-worker takes the cloth, and gives it its first cut or sheering: then the carders resume it, and, after wetting, give it as many more courses with the teazle, as the quality of the stuff requires, always observing to begin against the grain of the hair, and to end with it; as also to begin with a smoother thistle, proceeding still with one sharper and sharper, as far as the sixth degree.

The cloth next is sent to the dyer: when dyed it is washed in fair water, and the worker takes it again wet as it is, lays the nap with a brush on the table, and hangs it on the tenters; where it is stretched both in length and breadth sufficiently to smooth it, set it square, and bring it to its proper dimensions, without straining it too much; observing to brush it afresh, the way of the nap, while a little moist, on the tenters. When quite dry the cloth is taken off the tenters, and brushed again on the table, to finish the laying of the nap; after which it is folded, and laid cold under a press, to make it perfectly smooth and even, and give it a gloss.

Lastly, the cloth being taken out of the press, and the papers, &c. for glossing it removed, it is in a condition for sale or use. With regard to the manufacture of mixt cloths, or those wherein the wools are first dyed and then mixt, spun and woven of the colours intended, the process, except what relates to the colour, is mostly the same with that just represented.

CLOUD, in physiology, a collection of vapours visibly suspended in the atmosphere; being a congeries chiefly of watery particles, drawn up from the sea and land by the solar or subterraneous heat, or both, in vapour. See METEOROLOGY.

CLOVE TREE. See CAROPHYLLUS.

CLOVE, a term used in weights. Seven pounds of wool make a clove.

In Essex eight pounds of cheese and butter go to the clove.

CLOVER-GRASS. See TRIFOLIUM.

CLOUGH, or *draught*, among traders, an allowance of two pounds to every three hundred weight, for the turn of the scale, that the commodity may hold out when sold by retail.

CLUPEA, or *herring*, in ichyology, a genus belonging to the order of abdominales. The upper jaw is furnished with a serrated mystache; the branchiostege membrane has eight rays; a scaly serrated line runs along the belly from the head to the tail: and the belly-fins have frequently nine rays. There are 11 species, viz.

1. The clupea harengus, or common herring, has no spots, and the under jaw is longer than the upper one. A herring dies immediately after it is taken out of the water; whence the proverb, As dead as a herring. Herrings are found from the highest northern latitudes yet known, as low as the northern coasts of France; none are found more southerly. They are met with in vast shoals on the coast of America, as low as Carolina. In Chesapeak-bay is an annual inundation of these fish, which cover the shore in such quantities as to become a nuisance. The great winter rendezvous of the herring is within the arctic circle: there they continue for many months, in order to recruit themselves after the fatigue of spawning; the seas within that space swarming with insect food in a far greater degree than those of our warmer latitudes. An immense number of them begin to appear off the Shetland isles in April and May; but these are only the forerunners of the grand shoal which comes in June; and their appearance is marked by certain signs, by the numbers of birds which follow to prey on them; but when the main body approaches, its breadth and depth are such as to alter the appearance of the very ocean. It is divided into distinct columns of five or six miles in length, and three or four in breadth, and they drive the water before them with a kind of rippling: sometimes they sink for the space of 10 or 15 minutes, and then rise again to the surface; and in fine weather reflect a variety of splendid colours.

The first check this army meets with in its march

southward is from the Shetland isles, which divide it into two parts; one wing takes to the east, the other to the western shores of Great Britain, and fill every bay and creek with their numbers; others pass on towards Yarmouth, the great and ancient mart of herrings: they then pass through the British channel, and after that in a manner disappear. Those which take towards the west, after offering themselves to the Hebrides, where the great stationary fishery is, proceed to the north of Ireland: here they meet with a second interruption, and are obliged to make a second division; one party takes to the western side, and is scarcely perceived, being soon lost in the immensity of the Atlantic; but the other, that passes into the Irish sea, rejoices and feeds the inhabitants of most of the coasts that border on it. These brigades, as we may call them, which are thus separated from the greater columns, are often capricious in their motions, and do not show an invariable attachment to their haunts.

They are full of roe in the end of June, and continue in perfection till the beginning of winter, when they deposit their spawn. The young herrings begin to approach the shores in July and August, and are then from half an inch to two inches long: those in Yorkshire are called *herring file*. Though we have no particularly authority for it, yet as very few young herrings are found in our seas during winter, it seems certain that they must return to their paternal haunts beneath the ice, to repair the vast destruction of their race during summer by men, fowl, and fish. Some of the old herrings continue on English coast the whole year: the Scarborough fishermen never put down their net but they catch a few; but the numbers that remain are not worth comparison with those that return. The Dutch are extravagantly fond of pickled herrings, but the art of curing them was invented in Flanders. There is as much joy in Holland on receiving the first buss of herrings (for which a premium is given), as the Egyptians show on the overflowing of the Nile.

2. The clupea sprattus, or sprat, has 13 rays in the back fin. It is a native of the European seas, and has a resemblance to the herring, but is smaller. They come into the river Thames in November, and leave it in March.

3. The clupea encrasiolus, or anchovy, has the upper jaw longer than the under one, and is about three inches long. They are taken in the Mediterranean, and brought here and pickled. The principal fishery is at Georgia, a small island west of Leghorn.

4. Clupea alosa, the shad, has a forked snout, and black spots on the sides. According to Belonius and Hasselquist, this is a fish of passage in the Nile. The latter says it is found in the Mediterranean near Smyrna, and on the coast of Egypt near Rosetta; and that in the months of December and January it ascends the Nile as high as Cairo, where the people stuff it with pot-marjoram; and when dressed in that manner, it will very nearly intoxicate the eater. In Great Britain the Severn affords this fish in higher perfection than any other river. It makes its first appearance there in May, but in very warm seasons in April: for its arrival sooner or later depends much on the temperature of the air. It continues in the river about two months, and then is succeeded by the variety called the twaite. The Severn shad is esteemed a very delicate fish about the time of its first appearance, especially in that part of the river that flows by Gloucester, where they are taken in nets, and usually sell dearer than salmon: some are sent to London, where the fishmongers distinguish them from those of the Thames by the French name alose. Whether they spawn in this river and the Wye is not determined; for their fry has not yet been ascertained. The old fish come from the sea into the river in full roe. In July and August multitudes of bleak frequent the river near Gloucester; some of them are as big as a small herring, and these the fishermen erroneously suppose to be the fry of the shad. Numbers of these are taken near Gloucester, in those months only, but none of the emaciated shad are ever caught in their return. The Thames shad does not frequent that river till the end of May or beginning of June, and is esteemed a very coarse and insiped sort of fish. The Severn shad is sometimes caught in the Thames, though rarely, and called allis by the fishermen in that river. About the same time, or rather earlier, the variety called, near Gloucester, the twaite, makes its appearance. It is taken in great numbers in the Severn, and is held in as great disrepute as the shad of the Thames. The differences between each variety are as follows: the true shad weighs sometimes 8 lb. but their general size is from 4 to 5 lb. The twaite, on the contrary, weighs from half a pound to 2 lb. which it never exceeds. The twaite differs from the shad only in having one or more round black spots on the sides; if only one, it is always near the gill; but commonly there are three or four, placed one under the other.

5. Clupea atherinoides has a shining line on each side, and small belly-fins. It is a native of Surinam.

6. Clupea mystus is shaped like a sword, and the fins at the anus are united. It is found in the Indian ocean.

7. Clupea sima has yellow fins, those of the belly being very small. The mouth is flat; the upper jaw is very short; the body is of a shining silver colour; and the fins are yellow. It is a native of Asia.

8. Clupea Sinensis is very like the common herring, but broader. It is a native of China, and has no teeth.

9. Clupea sternicla has no belly fins, and the body is broad. It is a native of Surinam.

10. Clupea thrissa has 28 rays in the fin at the anus. It is found in the Indian ocean.

11. Clupea tropica has a wedge-like tail, and a white, broad, compressed body. It is found at Ascension island.

CLUSIA, the *balsam-tree*, a genus of the polygamia monoecia class of plants, and in the natural method ranking under those plants the order of which is doubtful. The male calyx is tetraphyllous or hexaphyllous, with its leaflets opposite and imbricated; the corolla tetrapetalous or hexapetalous; the stamina numerous. The calyx and corolla of the female as in the male; the nectarium of antheræ or glandules coalited, including the germen. The capsule is quinquelocular, quinquevalved, and full of pulp. There are six species, all natives of America. The most remarkable is the

Clusia flava. It is pretty common in the British American islands, where the trees grow to the height of 20 feet, and shoot out many branches on every side, furnished with thick, round, succulent leaves placed opposite. The flowers are produced at the ends of the branches,

each having a thick succulent cover. They are succeeded by oval fruit. From every part of these trees there exudes a kind of turpentine, which is called in the West Indies hog gum; because they say, that when any of the wild hogs are wounded, they repair to these trees, and rub their wounded parts against the stem till they have anointed themselves with this turpentine, which heals all wounds. The plants are very tender, and in this country must be kept constantly in a stove.

CLUYTIA, a genus of the gynandria order, in the diœcia class of plants, and in the natural method ranking under the 38th order, tricoccæ. The male calyx is pentaphyllous; the corollo pentapetalous; the calyx and corolla of the female as in the male; the styles are three; and the capsule is trilocular with a single seed. There are 10 species, all natives of warm climates. They are evergreen shrubby plants, rising six or eight feet, with simple leaves, and greenish-white quinquepetalous flowers. They are propagated by cuttings in spring or summer, planting them in pots of light earth, plunged in a hot-bed. The plants must always be kept in a stove.

Cluytia clutheria. Dr. Wright in his account of the medicinal plants of Jamaica, says, that this species is the same as the cascarilla and clutheria of the shops. Other medical writers have supposed them to be distinct barks, and they are sold in the shops as different productions. Linnæus's croton cascarilla, Dr. Wright observes, is the wild rosemary shrub of Jamaica, the bark of which has none of the sensible qualities of the cascarilla.

CLYPEOLA, *treacle-mustard*, a genus of the siliculosa order, in the tetradynamia class of plants, and in the natural method ranking under the 39th order, siliquosæ. The silicula is emarginated, orbiculated, compressed plane, and deciduous. There are three species, natives of France, Italy, and the warm parts of Europe, but hardy enough to bear the winters in this country. One of them is an annual, and the others perennial plants; they are low and herbaceous, bearing spikes of white flowers.

CLYSTER. See MEDICINE.

CNEORUM, *widow-wail*, a genus of the monogynia order, in the triandria class of plants, and in the natural method ranking under the 38th order, tricoccæ. The calyx is tridentated; there are three equal petals, and a tricoccous berry. There is but one species, a little evergreen and very ornamental shrub, adorned with simple leaves, and tripetalous flowers of a pale yellow colour. It is propagated from seeds, and requires only to be kept free from weeds.

CNICUS, *blessed thistle*, a genus of the polygamia æqualis order, in the syngenesia class of plants, and in the natural method ranking under the 49th order, compositæ. The calyx is ovate, imbricated with spinous branched scales, and encircled with bracteæ. The flowrets are equal. There are nine species, of which the only remarkable one is that used in medicine under the name of carduus benedictus. This is an annual plant cultivated in gardens: it flowers in June and July, and perfects its seeds in autumn. For medical purposes it should be gathered when in flower, dried in the shade, and kept in a very dry airy place, to prevent its rotting or growing mouldy, which it is very apt to do. The leaves have a penetrating bitter taste, not very strong or durable; accompanied with an ungrateful flavour, which they are in a great measure freed from by keeping. Water extracts in a little time, even without heat, the lighter and more grateful parts of this plant; if the digestion is continued for some hours the disagreeable parts are taken up; a strong decoction is very nauseous and offensive to the stomach. Rectified spirit gains a very pleasant bitter taste, which remains uninjured in the extract. The virtues of this plant are little known in the present practice. The nauseous decoction is sometimes used to provoke vomiting; and a strong infusion to promote the operation of other emetics.

COACHMAN opening and partly destroying a parcel left in his coach, is guilty of felony.

COAK is used for exciting intense heats, for chemical purposes, or for smelting iron ore, and for operations in which common coal would be detrimental, as the drying malt. Coak is fossil coal previously charred by an operation similar to that by which charcoal is made.

COAL, or *pit-coal*, in mineralogy. The substances belonging to this genus are composed chiefly of carbon and bitumen. There are six species, (1.) *Jet:* this substance is found in France, Spain, Germany, Britain, and other countries. It is found in detached kidney-form masses, of various sizes, from an inch to seven or eight feet in length. The colour is full black: internal, glossy, opaque: not so brittle as asphaltum: texture striated; fracture conchoidal. Specific gravity 1.259. It has no smell except when heated, and then it resembles asphaltum in its odour. It melts in a strong heat, burns with a greenish flame, and leaves an earthy residuum. Becomes electric by friction; and when distilled it yields a peculiar acid.

(2.) *Cannel coal* is found in Lancashire, and in different parts of Scotland. The colour is black, opaque: structure sometimes slaty: texture compact: fracture conchoidal: brittle. Specific gravity 1.232 to 1.426. Does not stain the fingers. Kindles easily, and burns with a bright white flame like a candle, which lasts but a short me. It does not cake. See AMPELITES.

A specimen of Lancashire cannel coal, annalysed by Mr. Kirwan, contained

75.20	charcoal
21.68	maltha
3.10	alumina and silica
99.98	

A specimen of the slaty kind from Ayrshire, called splent coal, was composed of

47.62	charcoal
32.52	maltha
20.00	earths
100.14	

Cannel coal is susceptible of polish, and like jet, is often wrought into trinkets.

3. *Common coal.* This very useful combustible is never found in the primitive mountains, but only in the secondary mountains, or in plains formed of the same materials with them. It is always in strata, and generally alternates with clay, sandstone, or limestone.

The colour is black, more or less perfect. Lustre usually greasy or metallic. Opaque. Structure generally slaty. Texture often foliated. Fracture various. Specific gravity 1.25 to 1.37. Usually stains the fingers. Takes fire more slowly, and burns longer, than the last species. Cakes more or less during combustion.

Of this species there are many varieties. distinguished in Britain by the names of caking coal, rock coal, &c. These are too well known to require any description.

Mr. Kirwan analysed a variety of different kinds of coal. The result of the experiments may be seen by the following table:

Whitehaven coal.	Wigan.	Swansey.	Leitrim.	
57.0	61.73	73.53	71.43	charcoal.
41.3	36.7	23.14	23.37	maltha and asph.
1.7	1.57	3.33	5.20	earths.
100.00	100.00	100.00	100.00	

(4.) *Spurious coal* is generally found amidst strata of genuine coal. It is also called parrot coal in Scotland.

The colour is greyish black. Structure usually slaty. Texture earthy. Specific gravity 1.5 to 1.6. Generally explodes, and bursts when heated.

Composed of charcoal, maltha, and asphalt, and above .20 of stony matter.

(5.) *Anthracite.* This substance, as Dolomieu informs us, is found exclusively in the primitive mountains. It is commonly amorphous, sometimes crystallized in short hexagonal prisms. Colour black, or brownish black. Structure slaty. Fragments rhomboidal. Specific gravity 1.300. Often stains the fingers.

Burns precisely like the last species, and leaves .40 of white ashes. According to Dolomieu, it is composed of about

64.0 charcoal
32.5 silica
3.5 iron

100.0

(6.) *Kilkenny coal.* This mineral has been found in Hungary, Italy, France, Ireland, and Wales. It occurs in stratified masses, or in lumps nested in clay. The colour is black. Opaque. Texture foliated. Specific gravity 1.4 to 1.526. Often stains the fingers. Insoluble in acids. Deflagrates with nitre. Does not burn till wholly ignited, and then consumes slowly without emitting flame or smoke. It consists almost entirely of charcoal.

Coal, *small*, a sort of charcoal prepared from the spray and brushwood stripped off from the branches of coppice-wood, sometimes bound in bavins for that purpose, and sometimes charred without binding, and then it is called coming it together.

The wood they dispose on a level floor, and setting a portion of it on fire, they throw on more and more, as fast as it kindles, whence arises a sudden blaze, till all is burnt that was near the place. As soon as all the wood is thrown on, they cast water on the heap from a large scoop, and thus keep playing the heap of glowing coals, which stops the fury of the fire; while with a rake they spread it open, and turn it with shovels till no more fire appears. Then they shovel them up into great heaps, and when thoroughly cold, put them up in sacks, to be used by divers artificers to temper and anneal their several works.

[The method of procuring charcoal in America and other places where large timber is more plenty, is different; here it is common to place many cords of large wood in an upright position compactly together, and cover it with earth, leaving an opening to which fire may be introduced; it is then closed up, to prevent combustion, and in this way great quantities are procured. (*a*)

Coal-laws. Sea-coal brought into the Thames shall be sold by the chaldron, containing 36 bushels heaped up, according to the bushel sealed for that purpose at Guildhall.

All sellers of coals are to keep a lawful bushel, which bushel and other measures shall be edged with iron and sealed; and using others, or altering them, incurs a forfeiture of 50*l.*

Any purchaser dissatisfied with the measure of any coals, may, on delivery to him of the meter's ticket, have the same remeasured, by sending notice thereof to the seller, and to the land coal-meter's office for the district in which the coals were sold; on which a meter (not being the same under whose inspection the coals were originally measured) must, within two hours, attend to remeasure the coals, and shall remeasure the same sack by sack, in the presence of the seller and purchaser (if they attend), and also in the presence of a meter from the two other districts (whose attendance within London and Westminster is enforced by a penalty of 5*l.* but not in Surry); for this attendance the purchaser is to pay each coal-meter attending 6*d.* per chaldron. If the coals prove deficient measure, the seller shall forfeit 5*l.* for every bushel deficient, and also forfeit the coals to the poor. The meter under whose inspection the coals were measured at the wharf, shall also forfeit 5*l.* per bushel deficient, to be recovered (if not in five days) of the principal coal-meter; and coal-porters 2*s.* 6*d.* per bushel. The carman is to be paid 2*s.* 6*d.* for his horses, &c. for each hour, whilst the coals are remeasuring.

Any coal-factor receiving, or coal-owner giving, any gratuity for buying or selling any particular sort of coals, and selling one kind of coals for and as a sort which they really are not, shall forfeit 500*l.* 3 Geo. II. c. 26.

Owners or masters of ships shall not enhance the price of coals in the river Thames, by keeping turn in delivering coals there, under the penalty of 100*l.* 4 Geo. II. c. 30. Contracts between coal-owners, &c. and merchants of ships for restraining the buying of coals are void, and the parties shall forfeit 100*l.* 9 Ann. c. 28.

Wilfully and maliciously setting on fire any mine, pit, or delph of coal, or cannel-coal, is felony without benefit or clergy. 10 Geo. II. c. 32.

Setting fire to, demolishing, or otherwise damaging, any engine or any other thing belonging to coal-mines, is felony and transportation for seven years. 9 Geo. III. c. 29.

COAMINGS, in ship-building, are those planks which raise up the hatches higher than the rest of the deck, in which loop-holes for muskets to shoot out are usually made, in order to clear the deck when the ship is boarded by an enemy.

COASTING, that part of navigation where the places assigned are not far distant, so that a ship may sail in sight of land, or within soundings, between them. In this there are only required a good knowledge of the land, and the use of the compass and lead, or sounding-line.

COAT, or *coat of arms*, in heraldry, a habit worn by the ancient knights over their arms, both in war and tournaments, and still borne by heralds at arms. It was a kind of surcoat, reaching as low as the navel, open at the sides with short sleeves, sometimes furred with ermine and hair, upon which were applied the armories of the knights embroidered in gold and silver, and enamelled with beaten tin, coloured black, green, red, and blue: whence the rule never to apply colour on colour, or metal on metal.

Coats of arms and banners were never allowed to be worn by any but knights and ancient nobles.

COATS, in a ship, are pieces of tarred canvass put about the masts at the partners to keep out water. They are also used at the rudder's head, and about the pumps at the decks, that no water may go down there.

COBALT, in mineralogy, a mineral of a grey colour, first discovered by Brandt, the celebrated Swedish chemist, in 1733.

Bergman confirmed and extended the discovery of Brandt in the year 1780. In the year 1800 a new set of experiments were made upon it by the school of mines at Paris, in order to procure it perfectly pure, and to ascertain its properties when in that state. And in 1802 a new set of experiments were published by Thenard, which throw considerable light on its combinations with oxygen.

I. 1. Cobalt is of a grey colour with a shade of red, and by no means brilliant. Its texture varies according to the heat employed in using it. It is composed of plates, sometimes of grains, and sometimes of small fibres adhering to each other. It has scarcely any taste or smell. 2. Its specific gravity, according to Bergman and the school of mines at Paris, is 7.7; but Tassaert makes it 8.5384. 3. It is brittle, and easily reduced to powder; but if we believe Leonhardi it is somewhat malleable when red-hot. Its tenacity is unknown. 4. When heated to the temperature of 130 degrees Wedgewood it melts; but no heat which we can produce is sufficient to cause it to evaporate. When cooled slowly in a crucible, if the vessel is inclined the moment the surface of the metal congeals, it may be obtained crystallized in irregular prisms. 5. Like iron, it is attracted by the magnet; and from the experiments of Wenzel it appears, that it may be converted into a magnet precisely similar in its properties to the common magnetic needle.

II. When exposed to the air it undergoes no change, neither is it altered when kept under water; its affinity for oxygen is not sufficiently strong to occasion a decomposition of the water. When kept red-hot in an open vessel it gradually imbibes oxygen; and is converted into a powder at first blue, but which gradually becomes deeper and deeper, till at last it becomes black, or rather of so deep a blue, that it appears to the eye black. If the heat is very violent the cobalt takes fire, and burns with a red flame. From the experiments of Thenard it follows, that cobalt is capable of combining with three doses of oxygen at least, and of forming three distinct oxides, which may be exhibited in a separate state.

1. The protoxide of cobalt has a blue colour. It may be obtained by dissolving cobalt in nitric acid, and precipitating the cobalt from the solution by means of potass. The precipitate has a blue colour; but when dried in the open air it gradually becomes black. This black powder is to be kept for half an hour in that degree of heat known to manufacturers of iron utensils by the name of cherry-red. This heat expels the oxygen which it had absorbed in drying, and converts it into a fine blue colour. This oxide dissolves in acids without effervescence. The solution of it in muriatic acid, if concentrated, is green; but if diluted with water it is red. Its solution in sulphuric and nitric acids is always of a red colour. 2. When the protoxide of cobalt, newly precipitated from acids by potass, is exposed to the air, it gradually combines with an additional dose of oxygen, as Thenard ascertained by experiment, and assumes an olive-green colour; and by cautiously drying it without the aid of heat, it may be obtained in that state. This is the deutoxide of cobalt. When this oxide is treated with diluted muriatic acid, a moderate heat developes oxymuriatic acid gas, and a red-coloured solution is obtained. Hence we see that the deutoxide of cobalt loses a portion of its oxygen during its solution in muriatic acid. 3. When the protoxide or deutoxide of cobalt, newly precipitated from an acid, is dried by heating it in the open air, it assumes a flea-brown colour, which gradually deepens, till at last it becomes black. This is the peroxide of cobalt. It dissolves with effervescence in muriatic acid, and a great quantity of oxymuriatic acid gas is exhaled. Mr. Thenard considers the brown colour which the oxide of cobalt first assumes before it becomes black, as a tritoxide; but his experiments are not sufficient to decide that point.

With respect to the reddish precipitate which is sometimes obtained by precipitating cobalt from acids, and which has been considered as a peculiar oxide of cobalt, Mr. Thenard suspects, with reason, that it is a combination of the oxide of cobalt with arsenic acid.

III. 1. Cobalt does not combine with carbon nor hydrogen. 2. It cannot be combined with sulphur by fusion. But sulphuret of cobalt may be formed by melting the metal along with sulphur previously combined with potass. It has a yellowish-white colour, displays the rudiments of crystals, and can scarcely be decomposed by heat. 3. Phosphuret of cobalt may be formed by heating the metal red-hot, and then gradually dropping in small bits of phosphorus. It contains about one-fifteenth of phosphorus. It is white and brittle; and when exposed to the air, soon loses its metallic lustre. The phosphorus is separated by heat, and the cobalt is at the same time oxidated. This phosphuret is much more fusible than pure cobalt.

IV. Cobalt does not combine with azotic gas, nor muriatic acid gas.

V. Cobalt seems capable of combining with most of the metals, but its alloys are very imperfectly known. 1. It combines with small portions of gold; but the alloy scarcely differs from pure cobalt in its properties. 2. When two parts of cobalt and one of silver are melted together, the two metals are obtained separately after the process: the silver at the bottom of the crucible, and the cobalt above it. Each of them, however, has absorbed a small portion of the other metal: for the silver is brittle and dark-colour-

ed, while the cobalt is whiter than usual. 3. The alloy of iron and cobalt is very hard, and not easily broken. Cobalt generally contains some iron, from which it is with great difficulty separated. 4. The alloy of tin and cobalt is of a light violet colour, and formed of small grains. 5. It was supposed formerly that cobalt does not combine with lead by fusion; for upon melting equal parts of lead and cobalt together, both metals are found separate; the lead at the bottom, and the cobalt above. Indeed when this cobalt is melted with iron, it appears that it had combined with a little lead; for the iron combines with the cobalt, and the lead is separated. But Gmelin has shown that the alloy may be formed. He put cobalt in powder within plates of lead, and covered them with charcoal to exclude the air. He then applied heat to the crucibles containing the mixtures. Equal parts of lead and cobalt produced an alloy, in which the metals appeared pretty uniformly distributed, though in some places the lead predominated. It was brittle, and received a better polish than lead, which it resembled rather than cobalt; its specific gravity was 8.12. Two parts of lead and one of cobalt produced an uniform mixture, more like cobalt than lead, very little malleable, and softer than the last. Its specific gravity was 8.28. Four parts of lead and one of cobalt formed an alloy still brittle, and having the fracture of cobalt, but the polish of lead. It was harder than lead. Six parts of lead and one of cobalt formed an alloy more malleable, and harder than lead. Its specific gravity was 9.65. Eight parts of lead and one of cobalt was still harder than lead, and it received a better polish. It was as malleable as lead. Its specific gravity was 9.78.

COCCINELLA, in zoology, a genus of insects (see Plate XXXVI. Nat. Hist. fig. 132) of the order of coleoptera, the characters of which are these; the antennæ are subclavated; the palpi are longer than the antennæ, the last articulation heart-shaped; the body is hemispheric; the thorax and elytra are margined; the abdomen is flat. This genus is divided into sections, from the colour of the elytra, and of the spots with which they are adorned. The females, impregnated by the males, deposit their eggs, which turn to small larvæ, slow in their process, and enemies to the plant-louse. Those larvæ are frequently found upon leaves of trees covered with plant-lice. On the point of being metamorphosed they settle on a leaf by the hinder part of their body, then bend and swell themselves, forming a kind of hook. The skin extends, grows hard, and in a fortnight's time the chrysalis opens along the back. The insect in its perfect state receives the impressions of the air, that gives its elytra a greater degree of consistence. It seldom flies, and cannot keep long on the wing. Of all the different larvæ of the coccinella, the most curious is the white hedgehog; a name given it by M. de Reaumur, on account of the singularity of its figure, and the tufts of hair which render it remarkable. It seeks its food on the leaves of trees. After a fortnight it settles on one spot, and without parting with its fur, turns to a chrysalis; three weeks after which it becomes a coccinella. The slough appears nowise impaired by its transformation. M. de Reaumur has observed it on a plum-tree. It is likewise found upon the rose-tree. When the coccinella first arrives at the state of perfection, the colours of its elytra are very pale, nearly bordering upon white or cream-colour; and its elytra are very soft and tender, but soon grow hard, and change to very lively brilliant colours. Their eggs are of an oblong form, and of the colour of amber. This is not the cochineal insect: for that see Coccus.

COCCOLOBO, a genus of the trigynia order, in the octandria class of plants, and in the natural method ranking under the 12th order, holoraceæ. The calyx is quinquepartite and coloured; there is no corolla; the berry is formed of the calyx, and is monospermous. There are 19 species: that called uvifera, or sea-side grape (see Plate XXXIII. Nat. Hist. fig. 129.) It grows upon the sandy shores of most of the West India islands; where it sends up many woody stems, eight or ten feet high, covered with brown smooth bark, and furnished with thick, veined, shining, orbicular leaves, five or six inches diameter, standing upon short footstalks.

COCCULUS *Indicus*, the name of a poisonous berry, too frequently mixed with malt liquors, in order to make them intoxicating; but this practice is expressly forbidden by act of parliament. It is the fruit of the monospermum cocculus. Fishermen have a way of mixing it with paste: this the fish swallow greedily; and are thereby rendered lifeless for a time, and float on the water. The old women use it with staves-acre, for destroying lice in children's heads.

COCCUS, in zoology, a genus of insects belonging to the order of hemiptera. The rostrum proceeds from the breast; the belly is bristly behind; the wings of the male are erect; and the female has no wings. The species are 22, denominated principally from the plants they frequent. The most remarkable species are,

1. The coccus hesperidum, or greenhouse bug, which is oval, oblong, of a brown colour, covered with a kind of varnish: it has six legs, with a notch and four bristles at the tail. It infests orange-trees and other similar plants in greenhouses. When young it runs upon the trees; but afterwards fixes on some leaf, where it hatches an infinity of eggs, and dies. The male is a very small fly.

2. The coccus phalarides. The male of this species is small; its antennæ are long for its size; the feet and body are of a reddish colour, nearly pink, and sprinkled with a little white powder. Its two wings, and the four threads of its tail, are snow-white; and of those threads two are longer than the rest. It is to be found upon the species of gramen which Linnæus calls phalaris. The female contrives, along the stalks of that dog-grass, little nests, of a white cottony substance, in which she deposits her eggs. The small threads of her tail are scarcely perceptible.

3. The coccus cacti (see Plate XXXIII. Nat. Hist. fig. 130, 131), a native of the warmer parts of America, is the famous cochineal animal, so highly valued in every part of the world for the incomparable beauty of its red colour, which it readily communicates to wool and silk, but with much more difficulty to linen and cotton. This insect, like others, is of two sexes, but exceedingly dissimilar in their appearance. The female, which alone is valuable for its colour, is ill-shaped, tardy, and stupid: its eyes, mouth, and antennæ, are fixed so deep, and are so concealed in the folds of the skin, that it is impossible

to distinguish them without a microscope. The male is very scarce, and is sufficient for 500 females or more: it is active, small, and slender, in comparison with the female; its neck is narrower than the head, and still narrower than the rest of the body.

The cochineal insect may, in some circumstances, be compared to the silkworm, particularly in the manner of depositing its eggs. The insects destined for this purpose are taken at a proper time of their growth, and put into a box well closed, and lined with a coarse cloth, lest any of them should be lost; and in this confinement they lay their eggs and die. The box is kept close shut till the time of placing the eggs on the nopal, when, if any motion is perceived, it is a sufficient indication that the animalcule has life, though the egg is so minute as hardly to be perceived; and this is the seed placed on the foliage of the cactus cochenilifer, or Indian fig, known to the Spaniards by the name of nopal, the quantity contained in the shell of a hen's egg being sufficient for covering a whole plant. At Oaxaca cochineal insects are gathered in large quantities, and form a branch of commerce; the cultivation of these little creatures being there the chief employment of the Indians. In trade four sorts of cochineal are distinguished, mastique, campeschane, tetraschale, and sylvester; of which the first is accounted the best, and the last the worst. Its principal consumption is among the dyers.

4. The coccus ilicis, or that forming the kermes grains, inhabits the quercus coccifera of the southern parts of Europe. Both ancients and moderns seem to have had very confused notions concerning the origin and nature of the kermes; some considering it as a fruit, without a just knowledge of the tree which produced it; others taking it for an excrescence formed by the puncture of a particular fly, the same as the common gall observed upon oaks; but it was finally discovered that the kermes is in reality nothing else but the body of an insect transformed into the resemblance of a grain, berry, or husk, according to the course of nature. The progress of this transformation must be considered at three different seasons. In the first stage, at the beginning of March, an animalcule, no larger than a grain of millet, scarcely able to crawl, is perceived sticking to the branches of the tree, where it fixes itself, and soon becomes immoveable: at this period it grows most, and appears to swell and thrive with the sustenance it draws in by degrees. At the second stage, in April, its growth is completed; its shape is then round, and about the size of a pea: it has then acquired more strength, and the down which covered it is changed into dust; and seems to be nothing but a husk or a capsule, full of a reddish juice, not unlike discoloured blood. Its third state is towards the end of May, when the husk appears replete with small eggs, less than the seed of a poppy. These are properly ranged under the belly of the insect, progressively placed in the nest of down that covers its body, which it withdraws in proportion to the number of eggs. After this work is performed it soon dies, though it still adheres to its position; rendering a further service to its progeny, and shielding them from the inclemency of the weather, or the hostile attacks of an enemy. In a good season they multiply exceedingly, laying from 1800 to 2000 eggs, which produce the same number of animalcules. In France poor people gather the kermes, letting their nails grow in order to pick them off with greater facility.

5. The coccus lacca, or gum-lac animal, is a native of the East Indies. This species traverse the branches of the trees upon which they were produced, for some time, and then fix themselves upon the succulent extremities of the young branches. By the middle of January they are all fixed in their proper situation; and appear as plump as before, but show no other marks of life. The limbs, antennæ, and setæ of the tail, are no longer to be seen. Around their edges they are environed with a spissid subpellucid liquid, which seems to glue them to the branch: it is the gradual accumulation of this liquid which forms a complete cell for each insect, and is what is called gum-lac. About the middle of March the cells are completely formed, and the insect is in appearance an oval, smooth, red bag, without life, about the size of a small cochineal insect, emarginated at the obtuse end, full of a beautiful red liquid. In October and November we find about 20 or 30 oval eggs, or rather young grubs, within the red fluid of the mother. When this fluid is all expended the young insects pierce a hole through the back of their mother, and walk off one by one, leaving their exuviæ behind, which is that white membranous substance found in the empty cells of the stick-lac. The insects are the inhabitants of four trees: 1. Ficus religiosa, Linnæi; 2. Ficus indica, Linnæi; 3. Plaso, Hortus Malabaricus; and 4. Rhamnus jujuba, Linnæi. The insects generally fix themselves so close together, and in such numbers, that scarcely one in six can have room to complete her cell: the others die, and are eaten up by various insects. The extreme branches appear as if they were covered with a red dust, and their sap is so much exhausted, that they wither, and produce no fruit; the leaves drop off, or turn to a dirty black colour. A red medicinal gum is produced by incision from the plaso tree, so similar to the gum-lac, that it may readily be taken for the same substance. Hence it is probable that those insects have little trouble in animalizing the sap of these trees in the formation of their cells. The gum-lac of this country is principally found upon the uncultivated mountains on both sides the Ganges, where the only trouble in procuring it is in breaking down the branches, and carrying them to market. The lac is of a deep red colour.

6. Coccus polonicus, an insect which may properly enough be called the cochineal of the northern part of the world. As the cochineal loves only the hot climates, this creature affects only the cold ones. Though collected for the use of the dyers, it is greatly inferior to the true cochineal. It is commonly known by the name of scarlet grain of Poland. It is to be met with not only in Poland, but in many of the northern countries. It is found affixed to the root of a plant, and usually to plants of that species thence called polygonum cocciferum. Towards the end of June the coccus is in a fit state to be gathered. Every one of these creatures is then nearly of a spherical form, and of a fine violet colour. Some of them, however, are not larger than poppy-seeds, but others are the size of a pepper corn; and each of them is lodged, either in part or entirely, in a sort of cup like that of an acorn. On some plants are found only one or two of these, and on others more than forty: and they are sometimes placed near the origin of the stalks of the plants.

COCCYX, or *coccygis os*, in anatomy, a bone situated at the extremity of the os sacrum. See ANATOMY.

COCHINEAL. See COCCUS.

This article is esteemed a great cordial, sudorific, alexipharmic, and febrifuge; and much used by dyers and painters, the high crimson colour it affords being scarcely equalled by any thing; and making, according to their different management of it, all the degrees and kinds of red.

COCHLEA, in anatomy, the third part of the labyrinth of the ear. See ANATOMY.

COCHLEARIA, *scurvy-grass*, a genus of the siliculosa order, in the tetradynamia class of plants; and in the natural method ranking under the 39th order, siliquosa. The silicula is emarginated, turgid, and scabrous; with the valves gibbous and obtuse. There are eight species; the most remarkable of which are,

1. Cochlearia Anglica, or garden scurvy-grass, it grows naturally on the sea shore, in the north of England and in Holland, but is cultivated for use in the gardens near London. It has a fibrous root, from which arise many round succulent leaves, which are hollowed like a spoon; the stalks rise from six inches to a foot high. The flowers are produced in clusters at the end of the branches, consisting of four small white petals. This plant is propagated by seeds, which should be sown in July: in spring they will be fit for use. Scurvy-grass is a pungent stimulating medicine, capable of dissolving viscid juices, opening obstructions of the viscera and the more distant glands, and promoting the more fluid secretions. It is particularly celebrated in scurvies, and is the principal herb employed in these disorders in the northern countries.

2. Cochlearia armoracia, or horse-radish, is so well known as to need no description. It is propagated by cuttings or buds from the sides of old roots. The root has a quick pungent smell, and penetrating acrid taste; it nevertheless contains in certain vessels a sweet juice, which sometimes exudes on the surface. By drying it loses all its acrimony, becoming first sweetish, and then almost insipid: if kept in a cool place, in sand, it retains its qualities for a considerable time. The medical effects of it are, to stimulate the solids, attenuate the juices, and promote the fluid secretions: it seems to extend its action through the whole habit, and to affect the minutest glands. It has frequently done service in some kinds of scurvies, and other chronic disorders proceeding from a viscidity of the juices or obstructions of the excretory ducts. Sydenham recommends it likewise in dropsies, particularly those which follow intermittent fevers. Both water and rectified spirit extract the virtues of this root by infusion, and elevate them in distillations: along with the aqueous fluid an essential oil rises, possessing the whole taste and pungency of the horse-radish.

COCHLITES, in natural history, an appellation given to the petrified shells of snails.

COCK. See PHASIANUS.

COCK-BOATS, those used only in rivers, or near the shores.

COCK'S-COMB. See CELOSIA.

COCK-PIT, in a ship of war, a place on the lower floor or deck, abaft the main-capstan, laying between the platform and the steward's room, where are partitions for the purser, surgeon, and his mates.

COCK-SWAIN, or *coxon*, an officer on board a ship of war, who has the care of the barge and all things belonging to it, and must be also ready with his crew to man the boat on all occasions: he sits at the stern of the boat, and steers.

COCK-WATER, among miners, a stream of water, brought into a trough, to wash away the sand from tin ore, while stamping in the middle.

COCKETT, *cockettum*, *cocketum*. The custom-house seal, or the office where goods to be wooden shivers, to keep them from splitting and galling by the pin of the block.

COCKETT, *cockettum*, *cocketum*. The custom-house or the office where goods to be transported are first entered, and pay their custom; and are to have a cockett, signifing that their merchandises are customed, and may be discharged, See CUSTOM-HOUSE.

COCOS, in botany, a genus belonging to the natural order of palmæ. It is of the monoecia hexandria. The calyx of the male is tripartite; the corolla tripetalous, with six stamina. The calyx of the female quinquepartite; the corolla tripetalous; the stigmata three; and the plum coriaceous. There are five species. The principal is,

Cocos nucifera, the cocoa-nut tree. It is supposed to be a native of the Maldive, and some desert islands in the East Indies, and thence to have been transported to all the warm parts of America: for it is not found in any of the inland parts, nor any where far distant from settlements. It frequently rises 60 feet high. The body of the trunk, which generally leans to one side, occasioned by the great weight of nuts it sustains when young, is the exact shape of an apothecary's large iron pestle, being of an equal thickness at top and at bottom, but some what smaller in the middle; its colour is of a pale brown throughout, and the bark smooth. The leaves or branches are often 14 or 15 feet long, about 28 in number, winged of a yellow colour, straight and tapering. The pinnæ are green, often three feet long next the trunk, but diminshing in length towards the extremity of the branches, which are fastened at top by brown stringy threads that grow out of them, of the size of ordinary packthread, and are interwoven like a web. The nuts hang at the top of the trunk, in clusters of a dozen each. Each nut, next the stem, has three holes closely stopped; one being wider and more easily penetrated than the rest. When the kernel begins to grow it incrusts the inside of the nut in a blueish, jelly-like substance: as this grows harder the inclosed liquid, distilled into the nut from the roots, becomes somewhat acid; and the kernel, as the nut ripens, becomes still more solid, and at length lines the whole inside of the nut for above a quarter of an inch thick, being as white as snow, and of the flavour of a filberd. The quantity of liquor in a full grown nut is frequently a pint and upwards. The husky tegument of the nut consists of strong, tough, stringy filaments, which, when removed from the fruit, resemble coarse oakum. The leaves are wrought into brooms, hammocks in form of nets, mats, sacks, and other useful utensils. The tree is propagated by planting the nuts, which in six or eight weeks will come up, provided they are

fresh and thoroughly ripe; but this is what few of them are when brought into this country: for they are always gathered before they are ripe, that they may keep during the passage. The best way, therefore, would be to gather such nuts as are thoroughly ripe in their native country, and plant them in a tub of dry sand, to keep them from the vermin during the passage. Here they will frequently sprout, which will be an advantage, as they may then be immediately planted in pots of earth, and plunged in the bark-stove.

COCTION, a general term for all alterations made in bodies by the application of fire or heat: of this there are various species, as maturation, friction, assation, elixation, ustion, &c. See FRICTION, &c. and also the articles PHARMACY and DECOCTION.

COD. See GADUS.

CODE, a collection of the laws and constitutions of the Roman emperors, made by order of Justinian. The code is accounted the second volume of the civil law, and contains 12 books, the matter of which is nearly the same with that of the digests, especially the first eight books; but the style is neither so pure, nor the method so accurate, as that of the digests: and it determines matters of daily use, whereas the digests discuss the more abstruse and subtile questions of the law, giving the various opinions of the ancient lawyers.

CODICIL. See WILL.

COECUM. See ANATOMY.

COEFFICIENTS, in algebra, such numbers, or given quantities, as are put before letters, or unknown quantities, into which letters they are supposed to be multiplied: thus, in $3a$, of bx, or cxx; 3 is the coefficient or $3a$, b of bx, and c of cxx. When no number is prefixed, unity is supposed to be the coefficient; thus 1 is the coefficient of a or of b. See ALGEBRA.

COEFFICIENT *of any generating term in fluxions*, is the quantity arising from the division of that term by the generated quantity.

COELIAC ARTERY. See ANATOMY.

COELIAC PASSION. See MEDICINE.

COELIAC VEIN, in anatomy, that running through the intestinum rectum, along with the cœliac artery. See ANATOMY.

COENOBITE, in church history, an order of monks in the primitive christian church. They were so called απο του κοινου βιου, from living in common, in which they differed from the anachorites, who retired from society.

COEUR, in heraldry, a short line of partition in pale, in the centre of the escutcheon, which extends but a little way, much short of the top and bottom, being met by other lines, which form an irregular partition of the escutcheon.

COFFEA, the *coffee-tree:* a genus of the monogynia order, in the pentandria class of plants: and in the natural method ranking under the 47th order, stellatæ. The corolla is funnel shaped; the stamina above the tube; the berry inferior, dispermous; the seeds arillated, or having a proper exterior covering dropping off of its own accord. There are 10 species, but that which is most worthy of attention is supposed to be a native of Arabia Felix. (See Plate XXXVI. Nat. Hist. fig. 133.) The coffea Arabica seldom rises more than 16 or 18 feet in height; the main stem grows upright, and is covered with a light-brown bark: the branches are produced horizontally and opposite, crossing each other at every joint. The leaves also stand opposite; and when fully grown are about four or five inches long, and two broad in the middle, decreasing toward each end; the borders are waved, and the surface is of a lucid green. The flowers are produced in clusters at the root of the leaves, sitting close to the branches; they are tubulous, and spread open at the top, where they are divided into five parts: they are of a pure white, and have a grateful odour, but are of short duration. The fruit, which is the useful part, resembles a cherry. It grows in clusters, and is ranged along the branches under the axillæ of the leaves, of the same green as the laurel, but something longer. When it comes to be of a deep red, it is gathered for exportation.

The coffee-tree is cultivated in Arabia, Persia, the East and West Indies, the isle of Bourbon, and several parts of America. It is also raised in botanic gardens in several parts of Europe. It delights particularly in hills and mountains, where its root is almost always dry, and its head frequently watered with gentle showers. It prefers a western aspect, and ploughed ground without any appearance of grass. The plants should be placed at eight feet distance from each other, and in holes twelve or fifteen inches deep. If left to themselves, they would rise to the height of 16 or 18 feet; but they are generally stinted to five for the convenience of gathering their fruit with the greater ease. Thus dwarfed, they extend their branches so, that they cover the whole spot round about them. They begin to yield fruit the third year, but are not in full bearing till the fifth. With the same infirmities that most other trees are subject to, these are likewise in danger of being destroyed by a worm or by the scorching rays of the sun. The hills where the coffee-trees are found have generally a gravelly or chalk bottom. In the last, it languishes for some time and then dies, in the former its roots, which seldom fail of striking between stones, obtain nourishment, and keep the tree alive and fruitful for 30 years. This is nearly the period for plants of the coffee-tree. The proprietor, at the end of that time, not only finds himself without trees, but has his land so reduced, that it is not fit for any kind of culture; and unless he is so situated that he can take a spot of virgin land, to make himself amends for that which is totally exhausted by the coffee-trees, his loss is irreparable.

The coffee-tree is sometimes cultivated in European gardens; but it requires a stove. It makes a fine appearance at all seasons of the year, but especially when in flower, and when the berries are red, which is generally in the winter, so that they continue a long time in that state. It is propagated from the berries; but they must be planted immediately when gathered from the tree, for they loose their vegetative quality in a very short time.

COFFER, in fortification, a hollow lodgment across a dry moat, from six to seven feet deep, and from 16 to 18 broad, the upper part being made of pieces of timber, raised two feet above the level of that moat: which little elevation has hurdles, laden with earth, for its covering, and serves as a parapet with embrasures. The besieged generally make use of these coffers to repulse the

besiegers, when they attempt to pass the ditch: they are distinguished only by their length from the caponiers, which are likewise somewhat less in breadth; and differ from the traverse and gallery, in that these are made by the besiegers, and the coffer by the besieged. To save themselves from the fire of these coffers the besiegers epaule, or throw up the earth, on that side towards the coffer.

COFFERER *of the king's household*, next under the comptroller, who superintends and pays the other officers of the household their wages.

COGGSHALL'S *sliding-rule*. See SLIDING-RULE.

COGNATION, in the civil law, a term for that line of consanguinity which is between males and females, both descended from the same father; as agnation is for the line of parentage between males only descended from the same stock. In France, for the succession to the crown, they follow agnation; in England, Spain, &c. cognation: women coming to the succession according to the degree of proximity, in default of males, or their descendants, from branch to branch.

COGNISOR, or *connusor*, he that passeth or acknowledgeth a fine of lands or tenements to another. Cognisee, or conusee, is he to whom the fine is acknowledged.

COGNISANCE, sometimes signifies an acknowledgment of fine, and sometimes a power or jurisdiction; as cognisance of pleas is an ability to call a cause or plea out of another court, which no one can do but the king, except he can show charters for it.

COGNITIONIBUS MITTENDIS, a writ to one of the king's justices of the common pleas, or other that has power to take a fine, and who having taken it, delays to certify the same, commanding him to certify it.

COGNOVIT ACTIONEM, is an acknowledgment by a defendant, or confession that the plaintiff's cause of action is just; and who, to save law expenses, suffers judgment to be entered against him; in this case the confession generally extends to no more than is contained in the declaration, with costs.

COHABITATION, in the civil law, denotes the state of a man and a woman who live together like husband and wife, without being legally married. By the common law of Scotland, cohabitation for a year and day, or a complete twelvemonth, is deemed equivalent to matrimony.

COHESION. The force called cohesion is inherent in the particles of all bodies, except caloric and light: for all bodies except these constantly exist in masses composed of an indefinite number of particles united together. This force possesses all the characters of affinity. 1. It acts only at insensible distances; for whenever we remove the particles of a body to a perceptible distance from each other, they cease to cohere altogether. 2. Cohesion is exceedingly various in different bodies: though in the same body, if other things be equal, it is always the same. Thus an iron rod is composed of particles of iron cohering so strongly, that it requires an enormous force to separate them. A smaller force is necessary to overcome the cohesion of lead, and a still smaller to separate the particles of chalk from each other. In short, there are scarcely two bodies whose particles cohere with the same force. The force of cohesion in solid bodies is measured by the weight necessary to break them, or rather to pull them asunder. Thus if a rod of glass is suspended in a perpendicular direction, and weights attached to its lower extremity till the rod is broken by them, the weight attached to the rod just before it broke is the measure of the cohesive force of the rod. We are indebted to Muschenbroeck for the most complete set of experiments hitherto made upon the cohesive force of solid bodies. Sickengen also has examined the cohesion of several of the metals with much accuracy. The results of the labours of the first of these philosophers, with regard to metals and wood, may be seen in the following table, in which the numbers denote the pounds avoirdupois which are just sufficient to tear asunder a rod of each of the bodies, whose base is an inch square.

I. METALS.	
Steel, bar	135,000
Iron, bar	74,500
Iron, cast	50,100
Copper, cast	28,600
Silver, cast	41,500
Gold, cast	22,000
Tin, cast	4,440
Bismuth	2,900
Zinc	2,600
Antimony	1,000
Lead, cast	860
II. WOODS.	
Locust-tree	20,100
Jujeb	18,500
Beech, oak	17,300
Orange	15,500
Alder	13,900
Elm	13,200
Mulberry	12,500
Willow	12,500
Ash	12,000
Plum	11,800
Elder	10,000
Pomegranate	9,750
Lemon	9,250
Tamarind	8,750
Fir	8,330
Walnut	8,130
Pitch-pine	7,656
Quince	6,750
Cypress	6,000
Poplar	5,500
Cedar	4,880

3. The nature of cohesion has been more happily explained by Boscovich than by any other philosopher. Indeed it forms the most beautiful and satisfactory part of his theory. According to him, the particles of bodies cohere together when they are placed in the limit of repulsion and attraction. Two particles, when situated at a certain distance from each other, repel each other mutually; this repulsion gradually diminishes as the distance between the particles increases, till at last when the distance reaches a certain magnitude, the repulsion ceases altogether. If the distance is increased ever so little, the particles now, instead of repelling, attract each other; and this attraction increases with the distance till at last

it reaches its maximum. From this point it gradually diminishes, till at last, when the particles have acquired a certain distance, it vanishes altogether. If the distance is increased ever so little beyond that distance, the particles now again repel each other. He supposes that the insensible distance between two particles is divided into an indefinite number of portions of alternate repulsions and attractions.

Boscovich supposes, that in all cases of cohesion the particles of the cohering body are so situated as to be in these limits of cohesion with respect to each other. According to this very ingenious theory, cohesion is not, properly speaking, a force, but an interval between two forces. And even if we were to modify the theory a little, still we must consider cohesion as the balancing of two opposite forces, either of which becomes prevalent according as the cohering particles are urged nearer each other or forced to a greater distance. Consequently if we were to speak with precision, cohesion is not itself a force, but the absence of a force. What has been hitherto called the force of cohesion, is the attraction which prevents the cohering particles from separating from each other, and which begins to act, or more precisely, which becomes prevalent, when the particles are urged to a greater distance from each other.

4. Boscovich has shown, in a very satisfactory manner, how all the varieties of cohesion may be produced by the differences in the size, figure, and density, of the cohering particles. It deserves attention, that in most cases the cohesive force of simple bodies is greater than that of compound bodies. To this indeed there are a great number of exceptions, but the observation holds in a variety of instances. All the metals cohere very strongly; the diamond probably coheres with no less force, if we can judge from its hardness: and the cohesion of sulphur is also very considerable. Thus if we except phosphorus, all the simple substances are remarkable for cohesion. Those of them which are in the state of elastic fluids must be excluded altogether; because in that particular state the particles, instead of being in the limit of cohesion, are actually repelled. In the earths, too, such of them at least as are found chrystallized in a state of purity, the cohesion is very strong. Thus the sapphire or chrystallized alumina, and rock crystal or crystallized silica, are always very hard, and exhibit a much stronger cohesion than lime-stone, or magnesian stones, which are composed of heterogeneous bodies. This remark, however, by no means applies to the metals; for in them the cohesion is very often encreased considerably by alloying them together. Thus the cohesoin of copper is doubled by alloying with one-sixth of its weight of tin, though the cohesion of the tin is scarcely one-sixth of that of the copper.

The cohesion of metals is greatly increased by forging them, and by drawing them out into wire. By this last operation gold, silver, and brass, have their cohesion nearly tripled; copper and iron more than doubled.

5. There are three states in which bodies exist exceedingly distinct from each other: the state of solids, of liquids, and of elastic fluids. In the first two states the particles cohere with more or less force; but the cohesion produces in them very different effects. In the first it prevents all relative motion among the particles themselves; in the second, this relative motion is left at full liberty. Hence in solid bodies the motion of one particle is followed by the motion of the whole mass; or if that is impossible, the cohesion is destroyed altogether. In liquids, on the contrary, the motion of one particle is not necessarily followed by that of the rest, neither does that motion destroy the cohesion. Boscovich has shown, that solidity and fluidity are the consequence of the figure of the cohering particles. If that figure is such that the particles may change their position without altering their relative distances, the consequence must be fluidity; because in that case there is nothing to oppose the motion of any individual particle. This happens when the particles are spherical; but if the figure is such that the particles cannot change their position without altering their relative distances, the bodies which they compose must be solids, because all relative motion of an individual particle is opposed by the attractions and repulsions of all the surrounding particles; for every motion must bring the particle out of the former limit of cohesion. This happens when the particles have the figure of parallelopipeds, or any other figure except that of spheres.

This explanation is exceedingly ingenious; but it would not be an easy task to explain by means of it all the phenomena of solidity and fluidity. How comes it, for instance, that the addition of a certain dose of caloric renders a body fluid which was before solid? If it be answered, that it acts by combining with the particles of the solid in such a manner as to render them spherical: how comes it, in that case, that gold and platina, metals which are ductile and malleable, properties which indicate a kind of approach to fluidity, and of course sphericity, in the particles of these metals,—how comes it that they require so much more caloric to render them fluid than bismuth or sulphur, which are altogether brittle? We must rather consider fluidity as a kind of solution in caloric, analogous to the solution of salts in water. But this explanation, though it would do very well in many instances, would lead us in others to difficulties as great as those which we are endeavouring to avoid.

The cohesion of liquids is often very considerable. According to sir Isaac Newton, it is nearly proportional to the density of the liquid. This holds pretty accurately in several instances: but it is not easy to ascertain the cohesion of a liquid with precision, because the particles slide upon each other; and the column of the liquid, whose cohesion we are measuring, always becomes smaller; till at last it consists only of a very small number of particles.

Viscid bodies have particles approaching to a spherical form; but deviating from it so far as to occasion a certain resistance to the relative motion of the particles.

Solid bodies are of two kinds: they may either resist all change of distance in their particles so strongly as not to be capable of comprehension or dilatation without a breach of cohesion; or they may admit of both to a certain degree with facility. The first of these constitutes hardness; the second constitutes softness if the practicles retain their new situation, or elasticity if they return again to their old position when the external force is removed. Ductility and malleability depend upon the same state as softness, only the particles require a greater force to make them change their situation, and assume a new one.

6. When a solid body is plunged into a liquid, if the particles of the liquid attract these of the solid with a greater force than these last particles attract each other, they are gradually carried off by the fluid, and combine with its particles, that is to say, the solid is gradually dissolved. Thus sugar is dissolved by water, and sulphur by oil. The particles of the solid thus dissolved are each of them surrounded and combined with a certain number of the particles of the liquid. Hence they must be arranged in the liquid in regular order, and at regular distances from each other. The greater the number of particles thus dissolved by the liquid, the smaller is the affinity by which each of them is retained, because it is surrounded by a smaller number of particles of the liquid. But the greater must be the force with which these particles are attracted towards each other, and of course tend to form the solid again by cohesion; because the greater the number of the particles of the solid dissolved in the fluid, the nearer they are to each other.

Thus it appears that the affinity between the fluid and solid diminishes with the quantity dissolved; but that the tendency to cohesion increases with that quantity. Consequently if the solution is supposed to go on, these two opposite forces must at last balance one another; and whenever that happens, the liquid can dissolve no more of the solid. If it did, the particles of the solid would in part cohere, and form a new portion of the solid again. Whenever this happens, the fluid is said to be saturated. The saturation of a fluid then does not mean that its affinity for the solid is satisfied, but that it is not greater than the tendency of the combined particles to cohere. Now when a liquid is saturated with a solid, if by any means we can abstract part of that liquid, the cohesive force of the particles of the solid must gain the superiority; and the consequence will be, that they will unite and form solid bodies anew, till their number is so much diminished, that their mutual attraction is again counterbalanced by the affinity of the liquid. Hence the reason that evaporation occasions the crystallization of those bodies which are held in solution by these liquids.

7. These different solid bodies differ excessively from each other in their tendency to cohesion; and this difference can only be ascertained by experiment. Thus the tendency to cohesion, and the force of cohesion, in silica, is so strong, that when it has been precipitated from a solution by evaporation, it cannot be dissolved again in the same liquid.

This tendency to cohesion, and the consequent insolubility of the compound, produce many of the most important phenomena of chemistry, as they occasion the various precipitations and decompositions which so often take place when different substances are mixed together. See Attraction, and Mechanics.

COHORT, *cohors*, in Roman antiquity, the name of part of the Roman legion, comprehending about six hundred men. There were ten cohorts in a legion, the first of which exceeded all the rest, both in dignity and number of men. When the army was ranged in order of battle, the first cohort took the right of the first line, and the rest followed in their natural order; so that the third was in the centre of the first line of the legion, and the fifth on the left, the second between the first and third, and the fourth between the third and fifth: the five remaining cohorts formed a second line, in their natural order.

COIF. The serjeants at law are otherwise called serjeants of the coif, from the lawn coif they wear on their heads, under their caps, when they are created, and always after.

COIN denotes all the several stamps and species of money in any nation. In earlier times, when the necessity of traffic put men upon the expedient of having money; and metals, on account of their firmness, cleanliness, and durableness, were chosen for that end; each person cut his metal into pieces of different sizes and forms, according to the quantity to be given for any merchandize, or according to the demand of the seller, or the quantity stipulated between them. It was usual then to go to market laden with metal, in proportion to the purchase to be made; and furnished with instruments for proportioning it, and with scales for dealing it out, according as occasion required. By degrees it was found more convenient to have pieces ready weighed: and as there were different weights required, all those of the same weight were distinguished with the same mark or figure. At length the growing commerce of money beginning to be disturbed with frauds, both in the weights and the matter, and the public authority interposed; and hence arose the first stamps, or impressions of money, to which succeeded the names of the moneyers, and at length the effigies of the prince, the date, legend, and other precautions to prevent the alteration of the specie: thus were coins completed, and gradually brought to their present perfection. See Coinage.

The following are Tables of the most remarkable Coins, both ancient and modern.

The Jewish Coins, and their value in English Money, are as follow:

																		l.	s.	d.
Gerah	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	0	0	$1\frac{9}{160}$
10	Bekah	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	0	1	$1\frac{11}{16}$
20	2	Shekel	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	0	2	$3\frac{3}{8}$
1000	100	50	Manch. Mina hebraica	-	-	-	-	-	-	-	-	-	-	-	-	-	-	5	14	$0\frac{3}{4}$

The Grecian coins, with their value and proportion.

| | | |

Coins of the French Empire.

The current coins of France were formerly the double louis (gold), the louis (gold), the piece of six livres (silver), that of three livers, the ecu (silver), twenty-four sols piece (silver), the twelve (silver), the six sols piece (silver), the large or double sol (of copper), the sol (of copper), and the half and quarter sol, or pieces of two and one liard. There are also ancient pieces made of copper and silver, denominated pieces of six liards, value one sol and a half.

According to the new system, an attempt has been made, with partial success, to introduce the following currency. The denomination of livre has been changed into that of franc, with an alteration, in the small proportion of only three pence to the louis. The franc is then assumed as the basis or unit of all their computations; and all values are reckoned upwards by tens, hundreds, and thousands of francs, and downwards by tenth parts and hundredth parts of francs.

Some coins have been put into circulation agreeable to this new system, viz. in silver pieces of 5 francs, in pieces of 30 sols, being the fourth of the franc, and in pieces of 15 sols, being the eighth of the franc; in copper pieces of 5 centimes (five hundredths) equal to the old sol, and of 10 centimes (ten hundredths) or one decime, equal to the double sol.

Value of the coinage of both nations.—As a primary principle, the traveller must recollect, that whenever the course of exchange between the two countries is at par, the French louis is to be considered as of equal value to the English pound sterling.

Existing English Coins.		French Value.
The guinea	is equal to	One louis and one 24 sols piece.
The crown piece	—	The six livre piece.
The half-crown	—	The three livre piece.
The shilling	—	The 24 sols piece.
The sixpence	—	The 12 sols piece.
The penny	—	The double sol.
The halfpenny	—	The sol.
The farthing	—	The deux liards.

Existing French Coins.		French Value.
The louis containing 24 livres or francs		One pound sterling.
The six livre piece	—	Five shillings.
The five franc piece	—	Four shillings and two pence.
The livre piece	—	Half-crown.
The 30 sol piece	—	Fifteen pence.
The 24 sol piece	—	One shilling.
The 15 sol piece	—	Seven pence half-penny.
The 12 sol piece	—	Six pence.
The 6 sol piece	—	Three pence.
The double sol	—	A penny.
The 6 liard piece	—	Three farthings.
The sol	—	One halfpenny.
The two liard piece	—	One farthing.
The liard	—	Half a farthing.

The livre or franc is a nominal value, equal to tenpence English. The tenth part of a franc is called a decime, and the hundredth part of a franc is called a centime.

Coins, Spanish. In Spain, and the states depending upon it, the gold coin is the pistole; above which are the double pistole and piece of four pistoles, and under it the half pistole; to which must be added the castillans of gold. The silver money is the piastre, or piece of eight rials, and its diminutions; as also the simple rial, with its diminutions. The copper coins are the ochavos, or octavos, which are of two kinds: the one equal to only four maravedis, and ordinarily called quarta; the other double this, and called double quarta: and lastly the maravedis. It must be observed, that in Spain they have new money and old; the old current in Sevil, Cadiz, Andalusia, &c. is worth 25 per cent. more than the new current at Madrid, Bilboa, St. Sebastian, &c. This difference is owing to their king Charles II. who, to prevent the exportation of money, raised it 25 per cent. which however he was able to effect only in part, several provinces still retaining the ancient rate.

Value and proportion of the Spanish coin.

Quarta, 4 maravedis

Octavo, or double quarta, 8 maravedis

Rial, old plata, equal to	0	0	$6\frac{3}{4}$
Piece of eight, or piastre	0	4	6
Pistole	0	16	9.3

Coins, Portuguese. Those of gold are the moeda d'oro, or as we call it, moidore, which is properly their pistole; above this are doppio moedas or double pistoles, and quadruple species equal to five pistoles. The silver coins are the crusada, pataca, or piece of eight, and vintem, of which they have two sorts, the one silver and the other billon. The ree is of copper, which serves them in accompts as the maravedis do the Spaniards.

Res, ree, or rez, equal to three-fifths of a farthing sterling

Vintem. 20 res

Cruzada, 26 vintems.

	l.	*s.*	*d.*
Mi-moeda, or half-pistole	0	13	6
Moeda d'oro, or pistole	1	7	0
Doppio moeda, or double pistole	2	14	0
Ducat of fine gold	6	15	0

Besides the above, they have also pieces of gold of the value of 3*l.* 12*s.*, 1*l.* 16*s.*, and other subdivisions.

Coins, Dutch. Those of silver are crowns or dollars, ducatoons, florins, and schellings, each of which has its diminution. The stiver is of billon: the duyt and penny, of copper.

	l.	*s.*	*d.*
Ducat of Holland	0	9	3.2
Ducatoon	0	5	5.59
Patagon, or rix dollar	0	4	4.28
The three-guilder piece, or sixty stivers	0	5	2.46
The guider-florin, or twenty stivers	0	1	8.08
The lion dollar	0	3	7.07

The schelling goes for six stivers, and the ortke is the fourth part of a stiver.

Coins, Flemish. Those of gold are imperials, rides or philips, alberts, and crowns; those of the silver are philips, rix dollars, patagons, schellings, and guldens; and those of copper, patards.

	l.	*s.*	*d.*
Groat, 8 patards			
Single stiver	0	0	$1\frac{1}{2}$
Schelling	0	0	$7\frac{1}{4}$
Gulden	0	2	0

	l.	s.	d.
Rix dollar, dollar, patagon	0	4	6
Imperial	0	11	9

COINS, German. Those of gold are ducats, which are of various kinds, oboli of the Rhine, and florins: of this last kind there are some likewise of silver, besides rix dollars and izelottes, which are all of that metal.

	s.	d.
Ducat of the bishop of Bamberg	9	3.2
Ducat of Hanover	9	2.7
Ducat of Brandenburg	9	3.2
Ducatoon of Cologn	5	5.02
Rix dollar or patagon of Cologn	4	4.53
Rix dollar or patagon of Leige	4	7.48
Rix dollar of Mentz	4	7.27
Rix dollar of Frankfort	4	6.53
Rix dollar of the Palatinate of Nuremberg	4	7.55
Rix dollar of Lunenburg	4	6.65
Old rix dollar of Hanover	3	6.03
Old bank dollar of Hamburgh	4	6.92
Rix dollar of Lubec	4	7.54
Gulden of Hanover	2	4.14
Gulden of Zell	2	3.07
Gulden of Brandenburg	2	3.81
Gulden of Saxony	2	4.12

COINS, Italian. The several states of Italy have several current moneys, though there are some common to all, such as the pistole of gold, and the ducatoon and florin of silver, which are of various weights, fineness, &c. The coins peculiar to Rome are the julios of silver, the pignatelle of billon, and the bayoco, demi-bayoco, and quadrine, of copper. Venice has its sequins of gold; its justins, or ducatoons, and derlingues, of silver: Naples, its carlins: Genoa its croisats; Savoy and Piedmont, lys, all silver: the last state has its papiroles and cavales of billon.

Gold coins of Italy.

	s.	d.
The sequin of Venice	9	5.7
The old Italian pistole	16	7.6
Pistole of Rome, Milan, Venice, Florence, Savoy, Genoa	16	6.7
Double ducat of Genoa, Venice, and Florence	18	7.7
Single ducate of the same places	9	3.8
Silver coins.		
The old ducat of Venice	3	4.50
The ducat of Naples	3	4.43
The ducat of Florence or Leghorn	5	4.62
The tarin, or fifth part of the ducat, of Naples	0	8.09
The carlin, or tenth part	0	4.04
The escudi, or crown, of Rome, or piece of ten julios, or one hundred bayocos	5	1
The teston of Rome, or piece of three julios	1	6.32
The julio of Rome	0	6.10
The croisat of Genoa	6	6.74
Justine of Venice	4	9
Derelingue, one-fourth of the justine	1	$2\frac{1}{4}$

COINS, Swiss, are ratzes and blazes of billon; the ratze equal to $\frac{1}{9}$ of a penny sterling: and the blaze of Berne, nearly equal to the ratze.

The German, French, and Italian coins, are current here.

COINS, Polish.

	s.	d.
The golden ducat	9	2.1
The old silver dollar of Dantzic	4	6.27
The old rix dollar of Thorn	4	5.85
The rix dollar of Sigismund III. and Uladislaus IV. kings of Poland	4	6.4
Abra	1	$0\frac{1}{5}$
Roup	0	$4\frac{3}{4}$
Groch	0	$0\frac{6}{6}$

COINS, Danish, are,

	s.	d.
The gold ducat	9	3.2
The horse	1	$1\frac{1}{2}$
The four-mark piece	2	8.23
Marc lubs	1	6
Schesdal, or two marks	3	0
Rix mark	0	11
Slet mark	0	9

COINS, Swedish. Those of copper are the roustique, alluvre, mark, and money.

	s.	d.
A gold ducat is equal to	9	3.2
An eight-mark piece of silver	7	2
A four-mark piece	2	7
A christine	1	$1\frac{1}{2}$
Caroline	1	$5\frac{1}{4}$

The Swedish money properly so called, is a kind of copper, cut into little square pieces, or plates, about the thickness of three English crowns, and stamped at the four corners with the Swedish arms; and current in Sweden for a rix dollar, or piece of eight.

COINS, Muscovite. The proper coins of Muscovy are,

	s.	d.
The copec of gold, worth	1	$6\frac{1}{11}$
Copec of silver, or denaing	0	1
Polusk	0	$0\frac{1}{2}$
Motofske	0	$0\frac{1}{4}$
The ruble of silver, valued at	4	6
The cheroonitz of gold, called ducat by foreigners	9	6

COINS, Turkish. The gold coins are zingerlees, worth two dollars two-thirds; and tomilees, worth two dollars and a half, reckoning each dollar at 108 aspers; the sultani, xeriff, and chequeens, each worth about 9*s.* 4*d.*, 5*d.*, or 6*d.*, sterling.

The silver ones are the asper, worth a trifle more than a farthing sterling; and the para, or medin, worth three aspers.

COINS of the coast of Barbary. Though the general currency in these parts is Spanish dollars, French crowns, Hungarian ducats, and the Turkish golden sultanins, there are some coins struck by the kings or deys in their different territories.

At Morocco, the metacals are a sort of gold ducats made by the Jews at their pleasure, so that their standard is very uncertain.

There are also the blanquille of silver, worth $2\frac{1}{4}$*d.*; and the filours of copper, eight of which go to a blanquille.

At Algiers, the gold coins are sultanins and aspers; and burbas, of which six go to an asper. The dubla is silver, and worth about 4*s.* 6*d.* The rubie, median, and

zian, are of gold, the first equal to 35 aspers, or 1*s.* 9*d.* and the last 100 aspers.

At Tunis, they have sultanins of gold, but heavier by one-third than those of Constantinople: the nasura of silver, cut nearly square: and dublas and burbas, of the same value with those of Algiers.

Coins, Persian, are either of silver or copper: of the first kind are the

	s.	*d.*
Abassi, equal to	1	$4\frac{1}{2}$
Mamoudi	0	$8\frac{1}{4}$
Shakee	0	$4\frac{1}{8}$

The copper coins are the casbequi, or cabsequi, equal to 5-12ths of a penny sterling. The telac, or cherasis, is of gold, but it has no currency among the merchants, being only a medal struck by every king of Persia upon his accession to the crown.

Coins, Chinese. Throughout the kingdom of China and Tonquin there are not properly any coins struck; instead of these they cut their gold and silver into little pieces, of different weights: those of gold are called goltschuts; those of silver the natives call leam, the Portuguese taels. Besides these they have a small money of lead mixed with the scum of copper, having holes in the middle to string them on for the ease of numbering; this species is called caxa, cas, and pitis; and the string, which usually holds 200, is called santa. There are two sorts of goltschuts, the one of 32 and 1-7th ounces, and the other but half as much. The tael, or leam, is equal to 6*s.* 8*d.* sterling. The caxa, cas, or pitis, is one-third of a farthing; 300,000 of them are only worth about 56 guilders and 5 stivers of Holland.

Coins of Japan. The Japanese strike coupants both of gold and silver; and copper pieces with holes in the middle, like those of China, six hundred of which make the tael. The other moneys, which they cut, like the Chinese, of different weights, are chiefly three: the largest of the weight of six reals, viz. 48 taels, the tael equivalent to 75 Dutch stivers; the second equal to 6 and a half, and the third to 1 and 1-16th.

Coupant of gold, weighs one ounce six drachms; its figure is a long oval, the longest diameter about four inches, and the shortest half an inch: worth 6*l.* 12*s.* 6*d.*

Other coupants of gold, near one-third of the former, amounting to about 2*l.* 4*s.* 2*d.* Coupant of silver current at 4*s.* 6*d.*

Copper money, seven-twelfths of a farthing.

Coins of Siam. In the dominions of Siam are struck gold pieces five or six grains heavier than the half-pistole of Spain: but these are rather pieces of curiosity, than of use in commerce. Their silver coin is the tical or baat: the diminutions of which are the mayon or seling, $\frac{1}{4}$ of the tical; the fouang, $\frac{1}{2}$ of the mayon; the page, $\frac{1}{4}$ of the fouang; and clam, $\frac{1}{2}$ of the page; there are also sompays, in value $\frac{1}{2}$ a fouang. The tical weighs 3 gross and 23 grains, which, reckoning the ounce of silver at $3\frac{1}{2}$ louis tournois, is 32 sols and 4 deniers of that money, as it weighs near half an ounce.

Coins of the coasts and islands of the Indies. The principal, and those most generally current, are pagodos, rupees, larins, fanos or fanoms, and coupans, each of which are struck both of gold and silver. Besides these, there are also particular coins: as at Goa, St. Thomases of gold; at Surat, Agra, and the rest of Indostan, the pecha, or pessa, and doudus, all of copper; the basarucos and chedas, of tin. The gold pagodo is common on all the coasts of Coromandel, and almost the only one in use in the trade carried on there. The English make them at Fort St. George, and the Dutch at Negapatnam, of the same standard and weight with those of the country. The value is 5*s.* The value of the silver pagodo is very different: the smallest are worth eight tangas, reckoning the tanga at 90 or 100 basarucos, 8*s.*

The gold rupee is worth 1*l.* 11*s.* 6*d.*

Silver rupee varies in fineness and value. There are three kinds current, viz. rupee sicca, worth at Bengal, 2*s.* 11*d.*

Rupee of Madras, 2*s.* $5\frac{1}{2}d.$

Rupee of Surat, 2*s.* 3*d.*

This is to be understood of the new rupees; for as to the old ones of each kind, the value is less; those of Madras are but equal to 1*s.* 11*d.* those of Surat 2*s.* and the siccas 2*s.* 4*d.*

Larin, in form of a cylinder, bent into two, and flatted at each end, worth 9*d.*

Fanoms of gold are of different fineness, weight, and value. The heaviest are not worth above 5*d.* or $5\frac{1}{2}d.$ and the lightest little more than five farthings.

The silver fanoms are not worth at most above 2*d.*

St. Thomas, equal to 9*s.*

Pecha or pessa of copper, worth about $\frac{1}{2}d.$

Doudou, somewhat less than $\frac{1}{2}d.$

Basaruco, 1-5th of a farthing.

Cheda of pewter is of two kinds: the one octagonal current at $1\frac{3}{4}d.$

The other round, at $\frac{1}{3}d.$

In the dominions of the Great Mogul are roupees, mamoudas, and pechas; the first, both of gold and silver; the second of silver alone; and the third, of copper. There are others struck by the princes tributary to him, particularly a silver piece of the king of Matoucha, worth $\frac{1}{2}d.$ a silver piece of the king of Ogden, worth 6*d.* a gold piece of the king of Achem, worth 1*l.* 3*s.* a gold piece of the king of Macasser, taken for a guilder.

Shells current for coins are, 1. Cowries, brought from the Maldives, and pass for $\frac{1}{1\,0\,3}$ of a penny sterling. The natives of the coast of Africa call them bouges. 2. Porcelaine, in America, a shell nearly on the same footing with the cowrie. 3. Zimbi, current particularly in the kingdoms of Angola and Congo.

Fruits current for coins are, 1. Cacao, among the Americans, fifteen of which are esteemed equivalent to a Spanish rial. 2. Maize, which has ceased to be current since the discovery of America by the Europeans. 3. Almonds, used in the East Indies, where cowries are not current. The value of these is higher or lower, according as the year is more or less favourable to this fruit; in a common year, an almond is worth about 1-20th part of a farthing.

For real utility the following very short table will answer almost all practical purposes with regard to coins as far as relates to Europe:

	French money.		English money.		
	Frs.	*Cts.*	*L.*	*s.*	*d.*
A florin of Germany	2	20	0	1	10
A florin of Austria	2	65	0	2	2

	French money.	English money.
Rix dollar of Prussia	4 0	0 3 4
Dollars of North America	5 40	0 4 6
Guinea of England	25 0	1 1 0
Rix dollar of Denmark	5 70	0 4 9
Piastre of Spain	5 30	0 4 5
Lere of Italy	0 85	0 0 8½
Scuds of Rome	5 53	0 4 7
Ducat of Naples	4 30	0 3 7
Ronble of Russia	4 5	0 3 4
Rix dollar of Sweden	5 80	0 4 10½

[Coins, American, or Federal coin. Those of gold are the eagle, the half eagle, the quarter eagle; the silver coins are the dollar, the half dollar, the quarter dollar, the dime, and the half dime; the copper, are the cent and half cent.

Gold.		*L.*	*s.*	*d.*	
Eagle, or 10 dollars,		2	5	0	sterling.
Half eagle, or 5 dollars,		1	2	6	
Quarter eagle, or 2 dollars 50 cents,			11	3	
Silver.					
Dollar	100 cts.		4	6	
Half dollar	50		2	3	
Quarter dollar	25		1	1.5	
Dime	10			5.4	
Half dime	5			2.7	
Copper.					
Cent and half cent. (*a*)					

Coin, in architecture, a kind of dye cut diagonally, after the manner of a flight of a stair-case, serving at bottom to support columns in a level, and at top to correct the inclination of an entablature supporting a vault.

Coin is also used for a solid angle composed of two surfaces inclined towards each other: whether that angle be exterior, as the coin of a wall, a tree, &c. or interior, as the coin of a chamber or chimney.

COINAGE, or Coining, the art of making money, as performed either by the hammer or mill. Formerly the fabric of coins was different from what it is at present. They cut a large plate of metal into several little squares, the corners of which were cut off with sheers. After having shaped these pieces, so as to render them perfectly conformable in point of weight to the standard piece, they took each piece in hand again, to make it exactly round, by a gentle hammering. This was then called a planchet, and it was fit for immediate coining. The engravers then prepared, as they still do, a couple of steel masses in form of dyes, cut and terminated by a flat surface, rounded off at the edges. They engraved or stamped on them the hollow of a head, a cross, a scutcheon, or any other figure, according to the custom of the times, with a short legend. As one of these dyes was to remain dormant, and the other moveable, the former ended in a square prism; that it might be introduced into the square hole of the block, which, being fixed very fast, kept the dye as steady as any vice could have done. The planchet of metal was horizontally laid upon this inferior mass, to receive the stamp of it on one side, and that of the upper dye, wherewith it was covered, on the other. This moveable dye, having its round engraved surface resting upon the planchet, had at its opposite extremity a flat, square, and larger surface, upon which they gave several heavy blows, with a hammer of an enormous size, till the double stamp was sufficiently in relievo, impressed on each side of the planchet. The strong tempering which was and is still given to the two dyes, rendered them capable of bearing those repeated blows.

This art, however, has been improved and rendered very expeditious, by several ingenious machines, and by a wise application of the surest physical experiments to the methods of fining, dyeing, and stamping the different metals. The three finest instruments the mint-men use, are the laminating engine; the machine for making the impressions on the edges of coins; and the mill. After they have taken the laminæ, or plates of metal, out of the mould into which they are cast, they do not beat them on the anvil as was formerly done, but make them pass and repass between the several rollers of the laminating engine, which being gradually brought closer and closer to each other, at last give the lamina its uniform and exact thickness. Instead of dividing the lamina into small squares, they at once cut clean out of it as many planchets as it can contain, by means of a sharp steel trepan, of a roundish figure, hollow within, and of a proportionable diameter to shape and cut off the piece at one and the same time. After these planchets have been prepared and weighed with standard pieces, filed or scraped to get off the superfluous part of the metal, and then boiled and made clean, they arrive at last to the machine (Plate XXXII. fig. 9.), which marks them upon the edge; and finally at the mill (fig. 10.), which squeezing each of them singly between two dyes, brought near each other with one blow, forces the two surfaces or fields of the piece to fill exactly all the vacancies of the two engraved figures.

The principal pieces of the machine (fig. 9.) to stamp coins on the edge, are two steel lamina, about a line thick. One half of the legend, or of the ring, is engraven on the thickness of one of the laminæ, and the other half on the thickness of one of the other; and these two laminæ are straight, although the planchet marked with them is circular. When they stamp a planchet, they first put it between the laminæ in such a manner, as that these being each of them laid flat upon a copper-plate, which is fastened upon a very thick wooden table, and the planchet being likewise laid flat upon the same plate, the edge of the planchet may touch the two lamina on each side, and in their thick part. One of these laminæ is immoveable, and fastened with several screws; the other slides by means of a dented wheel, which takes into the teeth that are on the surface of the lamina. This sliding lamina makes the planchet turn in such a manner, that it remains stamped on the edge, when it has made one turn. Only crown and half-crown pieces are thick enough to bear the impression of letters on their edge.

The coining engine or mill (fig. 10.) is so convenient, that a single man may stamp 20,000 planchets in one day. Gold, silver, and copper planchets, are all of them coined with a mill, to which the coining squares (fig. 11.) commonly called dyes are fastened; that of the face under, in a square box furnished with male and female screws, to fix and keep it steady, and the other above in a little box with similar screws, to fasten the coining square. The planchet is laid flat on the square of the effigy, which is dormant; and then they immediately pull the bar of the mill by its cords, which causes the screws set

within it to turn. This enters into the female screw, which is in the body of the mill; and turns with so much strength, that by pushing the upper square upon that of the effigy, the planchet, violently pressed between both squares, receives the impression of both at one pull, and in the twinkling of an eye. The planchet thus stamped and coined, goes through a final examination of the mint wardens, from whose hands it comes into circulation.

In the coining of medals, the process is the same in effect with that of money; the principal difference consisting in this: that money, having but a small relievo, receives its impression at a single stroke of the engine; whereas for medals, the height of this relievo makes it necessary that the stroke be repeated several times: to this end the piece is taken out from between the dyes, heated, and returned again; which process, in medallions and large medals, is repeated fifteen or twenty times before the full impression is given: care must be taken every time the planchet is removed, to take off the superfluous metal, stretched beyond the circumference, with a file. Medallions, and medals of a high relievo, are usually first cast in sand, on account of the difficulty of stamping them in the press, where they are put only to perfect them; because the sand does not leave them smooth, clear, and accurate enough.

Coinage, British. It was only in the reign of William III. that the hammer-money ceased to be current in England, where till then it was struck in that manner as in other nations. Before the hammer-specie was called in, the English money was in a wretched condition; having been filed and clipped by natives as well as foreigners, insomuch that it was scarcely left of half its value. The British coinage is now wholly performed in the Tower of London, where there is an establishment for it under the title of the mint. Formerly there were here, as there are still in other countries, the right of seignorage and brassage: but since the eighteenth year of king Charles II. there is nothing taken either for the king or for the expenses of coining; so that weight is returned for weight, to any person who carries his gold and silver to the Tower. The specie coined in Great Britain is esteemed contraband, and not to be exported: but all foreign specie may be sent out of the realm, as well as gold and silver in bars, ingots, dust, &c.

Counterfeiting the king's money, or bringing false money into the realm counterfeit to the money of England, clipping, washing, rounding, filing, impairing, diminishing, falsifying, scaling, lightening, edging, colouring, gilding; making, mending, or having in one's possession, any puncheon, counter-puncheon, matrix, stamp, dye, pattern, mould, edger, or cutting engine: all these incur the penalty of high treason. And if any person shall counterfeit any such kind of gold or silver, as is not the proper coin of the realm, but current therein by the king's consent, he shall be guilty of high treason.

If any person shall tender in payment any counterfeit coin, he shall for the first offence be imprisoned six months, for the second offence two years, and for the third offence shall be guilty of felony without benefit of clergy.

Blanching copper or other base metal, or buying or selling the same; and receiving or paying money at a lower rate than its denomination imports; and also the offence of counterfeiting copper half-pence and farthings; incur the penalty of felony, but within clergy. Counterfeiting coin not the proper coin of this realm, nor permitted to be current therein, is misprison of treason. A person buying or selling, or having in his possession, clippings or filings, shall forfeit 500*l.* and be branded in the cheek with the letter R. And any person having in his possession a coining-press, or casting bars or ingots of silver in imitation of Spanish bars or ingots, shall forfeit 500*l.*

A reward of 40*l.* is given for convicting a counterfeiter of the gold or silver coin; and 10*l.* for a counterfeiter of the copper coin. 16 Geo. II. and 13 Geo. III. c. 28 and 77.

Coining, in the tin-works, is the weighing and stamping the blocks of tin with a lion rampant, performed by the king's officer; the duty for every hundred weight being four shillings.

COIX, Job's-tears; a genus of the triandria order, in the monœcia class of plants; and in the natural method ranking under the 4th order, gramina. The male flowers grow in spikes remote from each other; the calyx is a biflorous, beardless glume. The calyx of the female is a biflorous glume: the corolla a beardless glume; the style bipartite; the seed covered with the calyx ossified. There are three species, the principal of which, the coix lacryma, is a native of the East Indies, and frequently cultivated in Spain and Portugal. It is an annual plant, rising two feet from a fibrous root, with two or three jointed stalks, and single, long, narrow leaves at each joint, resembling those of the reed. At the base of the leaves come out the spikes of flowers standing on short footstalks; the seeds greatly resemble those of gromwell, whence the plant has by some writers been called lithospermum. It may be propagated in this country by seeds brought from Portugal, and sown on a hot-bed; after which the young plants should be removed into a warm border, and planted two feet from each other. In Spain and Portugal the poor grind this plant in times of scarcity, and make a coarse kind of bread of them. The seeds are inclosed in small capsules about the bigness of an English pea, and of different colours. These are strung upon silk, and used instead of bracelets, by some of the poorer sort in the West Indies, particularly by the negroes.

COLARBASIANS, in church-history, Christian heretics, in the second century, who maintained the whole plenitude and perfection of truth and religion to be contained in the Greek alphabet, and that it was upon this account that Jesus Christ was called the alpha and omega: they rejected the Old Testament; and received only a part of St. Luke's gospel, and ten of St. Paul's epistles, in the New.

COLARIN, in architecture, the little frize of the capital of the Tuscan and Doric columns, placed between the astragal and the annulets; called also hypotrachelium, and sometimes cincture.

COLCHICUM, meadow-saffron: a genus of the trigynia order, in the hexandria class of plants, and in the natural method ranking under the 9th order, spathaceæ. The corolla is sexpartite, with its tube radicated, or having its root in the ground; there are three capsules, connected and inflated. There are three species; all bulbous-rooted perennials, possessing the singular

property of their leaves appearing at one time, and their flowers at another; the former rising long and narrow from the root in spring, and decaying in June; the flowers (which are monopetalous, long, tubular, erect, and six-parted) rise naked from the root in autumn, not more than four or five inches. Their colours afford a beautiful variety; being purple, variegated purple, white, red, rose-coloured, yellow, &c. with single and double flowers. They are all hardy plants, insomuch that they will flower though the roots lie out of the ground; but by this they are much weakened. The root of this plant is poisonous. When young and full of sap, its taste is very acrid; but when old, mealy and faint. Two drachms of it killed a large dog in 13 hours, operating violently by stool, vomit, and urine. One grain of it swallowed by a healthy man, produced heats in the stomach, and soon after flushing heats in different parts of the body, with frequent shiverings, followed by colicky pains; after which an itching in the lions and urinary passage was perceived; then came on a continual inclination to make water, a tenesmus, pain in the head, quick pulse, thirst, and other disagreeable symptoms. Notwithstanding these effects, however, an infusion of roots in vinegar, formed into a syrup with honey or sugar, proves a safe and powerful pectoral and diuretic, and is often of service in dropsies, &c. The virtues of colchicum seem much to resemble those of squills.

Colchicum variegatum, one of the three species abovementioned. Its roots are said to afford the hermodactyle of the apothecaries.

COLD. When caloric combines with our bodies, or separates from them, we experience, in the first case, the sensation of heat, in the second cold. When the hand is put upon a hot iron, part of the caloric leaves the iron, and enters the hand; this produces the sensation of heat. On the contrary, when the hand is put upon a lump of ice, the caloric rapidly leaves the hand and combines with the ice; this produces the sensation of cold. The sensation of heat is occasioned by caloric passing into our bodies; the sensation of cold by caloric passing out of our bodies. We say that a body is hot when it communicates caloric to the surrounding bodies; we call it cold when it absorbs caloric from other bodies. The strength of the sensations of heat and cold depends upon the rapidity with which the caloric enters or leaves our bodies; and this rapidity is proportional to the difference of the temperature between our bodies and the hot or cold substance, and the conducting power of that substance. The higher the temperature of a body is, the stronger a sensation of heat does it communicate; and the lower the temperature, the stronger a sensation of cold: and when the temperature is the same, the sensations depend upon the conducting power of the substance. Thus what in common language is called cold, is nothing else than the absence of the usual quantity of caloric. When we say that a substance is cold, we mean merely that it contains less caloric than usual, or that its temparature is lower than that of our bodies.

There has been philosophers, however, who maintained that cold is produced, not by the abstraction of caloric merely, but by the addition of a positive something, of a peculiar body, endowed with specific qualities. According to them, cold is a substance of a saline nature, very much resembling nitre, constantly floating in the air, and wafted about by the wind in very minute corpuscles, to which they gave the name of frigorific particles. They were induced to adopt this hyphothesis, because they could not otherwise account for the freezing of water. According to them, these frigorific particles insinuate themselves like wedges between the molecules of water, destroy their mobility, and thus convert water into ice. Dr. Black, by discovering the cause of the freezing of water, banished the frigorific particles from the regions of philosophy; because the advocates for them never brought any other proof for their existence than the convenience with which they accounted for certain appearances. Of course, as soon as these appearances were explained without their use, every reason for supposing their existence was destroyed. The only fact which gives any countenance to the opinion that cold is a body, has been furnished by the following very curious experiments of Mr. Pictet. Two concave tin mirrors being placed at the distance of $10\frac{1}{2}$ feet from each other, a very delicate air-thermometer was put into one of the foci, and a glass matrass full of snow into the other. The thermometer sunk several degrees, and rose again when the matrass was removed. When nitric acid was poured upon the snow (which increases the cold), the thermometer sunk five or six degrees lower. Here cold seems to have been emitted by the snow, and reflected by the mirrors to the thermometer, which could not happen, unless cold was a substance. The experiment is certainly highly interesting, and deserving a more accurate examination than has been hitherto bestowed on it. In order to explain it, we must recollect that caloric is constantly radiating from all bodies. It is evident that the temperature of the thermometer, like that of all other bodies, is maintained partly by the irradiation of caloric from the surrounding bodies. It must therefore, since it is placed in the focus of one of the mirrors, be affected by whatever body is placed in the focus of the other. If that body is colder than the surrounding bodies, less caloric will be eradiated from it, and thrown upon the thermometer; consequently the theranometer will be depressed till the deficiency is supplied by some other channel. Such nearly is the explanation of this singular fact offered by Prevost and Dr. Hutton; but it cannot be denied that this explanation, ingenious as it is, is very far from being satisfactory.

A very great degree of cold may be produced by mixing together different solids, which suddenly become liquid. But as such mixtures are often employed in chemistry, in order to be able to expose bodies to the influence of a low temperature, it will be worth while to enumerate the different substances which may be employed for that purpose, and the degree of cold which each of them is capable of producing. The first person who made experiments on freezing mixtures was Fahrenheit. But the subject was much more completely investigated by Mr. Walker, in a paper published in the Philosophical Transactions for 1795. Since that time several curious additions have been made by professor Lowitz, particularly the introduction of muriat of lime, which produces a very great degree of cold when mixed with snow. The experiments of Lowitz have been lately repeated and extended by Mr. Walker. The result of

all these experiments may be seen in the following table.

Table of freezing mixtures.

Mixtures.	parts.	Thermometer sinks.
Muriat of ammonia	5	From 50° to 10°
Nitre	5	
Water	16	
Muriat of ammonia	5	From 50 to 4
Nitre	5	
Sulphat of soda	8	
Water	16	
Nitrat of ammonia	1	From 50 to 4
Water	1	
Nitrat of ammonia	1	From 50 to 7
Carbonat of soda	1	
Water	1	
Sulphat of soda	3	From 50 to 3
Diluted nitric acid		
Sulphat of soda	6	From 50 to 10
Muriat of ammonia	4	
Nitre	2	
Diluted nitric acid	4	
Sulphat of Soda	6	From 50 to 14
Nitrate of ammonia	5	
Diluted nitric acid	4	
Phosphat of soda	9	From 50 to 12
Diluted nitric acid	4	
Phosphat of soda	9	From 50 to 21
Nitrat of ammonia	6	
Diluted nitric acid	4	
Sulphat of soda	8	From 50 to 0
Muriatic acid	5	
Sulphat of soda	5	From 50 to 3
Diluted sulphuric acid	4	
Snow	1	From 32 to 0
Common salt	1	
Muriat of lime	3	From 32 to—50
Snow	2	
Potash	4	From 32 to—51
Snow	3	
Snow	1	From 20 to—60
Diluted sulphuric acid	1	
Snow or pounded ice	2	From 0 to—5
Common salt	1	
Snow and diluted nitric acid		From 0 to—46
Muriat of lime	2	From 0 to—66
Snow	1	
Snow or pounded ice	1	From—5 to—18
Common salt	5	
Muriat of ammonia and nitre	5	
Snow	2	From—10 to—56
Diluted sulphuric acid	1	
Diluted nitric acid	1	
Snow or pounded ice	12	From—18 to—25
Common salt	5	
Nitrate of ammonia	5	
Muriat of lime	3	From—40 to—73
Snow	1	
Diluted sulphuric acid	10	From—68 to—91
Snow	8	

In order to produce these effects, the salts employed must be fresh chrystallized, and newly reduced to a very fine powder. The vessels in which the freezing mixture is made should be very thin, and just large enough to hold it, and the materials should be mixed together as quickly as possible.

COLD, in medicine, is found to be productive of inflammatory disorders, as coughs, pleuresies, peripneumonies, rhumatic pains, consumptions, &c. See MEDICINE.

COLDENIA, a genus of the tetragynia order, in the tetrandria class of plants; and in the natural method ranking among those of the dubious order. The calyx is tetraphyllous; the corolla funnel-shaped; the styles four; the nuts four with a fungous rind. There is but one species, a native of India. It is an annual plant, whose branches trail on the ground, extending about six inches from the root. They are adorned with small blue flowers growing in clusters, which come out from the wings of the leaves.

COLEOPTERA, among zoologists, the first order of insects, comprehending all those with four wings, the external pair of which are hard, rigid, and opake, and form a kind of case for the interior pair: add to this, that the mouth consists of two transverse jaws.

According to the Linnæan system, there are about 56 genera in this order, and in forming them special care is had to the antennæ. They are thus arranged, in Linnæus's general system.

1. A. *a* Club lamellate; scarabæus, lucanus, synodendron.

2. *b.* Club perfoliate; dermestes, melyris, byrrhus, silpha, tritoma, hydrophilus, tetraloma.

3. Club solid or inflated. Hister, bostrichus, anthrenus, nitidula, coccinella, curculio, pausus.

4. B. Antennæ moniliform; brentas, attelabus, erodius, staphylinus, zygia, meloe, tenebrio, cassida, opatrum, mordella, chrysomela, horia.

5. C. Antennæ filiform; apalus, mantecora, pimelea, gyrinus, cucujus, cryptocephalus, bruchus, ptinus, hispa, buprestis, necydales, lampyris, cantharis, noloxus elater, calopus, alurnus, carabus lytta.

6. D. Antennæ setaceous; serropalpus, cerambyx, septura, rhenomacer, zoniles, cucindela, dytiscus, forficula.

These animals are known, in English, by the general name of beetles: whereof authors have established (as above) 56 genera, from the different figures of their antennæ, or horns, and other general distinctions; such are the scarabæus, or beetle, properly so called, the dermestes, and the several other genera as above noted.

COLIC, a severe pain in the lower venter, so called because the disorder was formerly supposed to be seated in the colon. See MEDICINE.

COLISEUM, or COLISÆUM, in ancient architecture, an oval amphitheatre at Rome, built by Vespasian, wherein were statues representing all the provinces of the empire; in the middle of which stood that of Rome, holding a golden apple in her hand. This structure was so large, that it would hold near 100,000 spectators. When Titus dedicated it, he sacrificed above 4000 beasts of different kinds.

COLLAR, in Roman antiquity, a sort of chain put generally round the neck of slaves that had run away,

after they were taken, with an inscription round it, intimating their being deserters, and requiring their being restored to their proper owners, &c.

Collar, in a modern sense, an ornament consisting of a chain of gold, enamelled, frequently set with cyphers and other devices, with the badge of the order hanging at the bottom; worn by the knights of several military orders over their shoulders, on the mantle, and its figure drawn round their armories. Thus, the collar of the order of the garter consists of SS, with roses enamelled red, within a garter enamelled blue, and the George at the bottom.

Collar *of a ship*, a rope fastened about her beak-head, into which the dead-man's-eye is seized, that holds her main-stay. Also the rope which is wound about the main-mast head, to save the shrouds from galling, is also called a collar. See Dead-man's-eye.

Collar-*beam*, in architecture, a beam framed cross betwixt two principal rafters.

Collar *of a plough*, an iron ring fixed on the middle of the beam, wherein are inserted the tow and bridle chains. See Plough.

COLLATERAL *point*, in cosmography, the intermediate points of those between the cardinal points.

Collateral, those relations which proceed from the same stock, but not in the same ascendants or descendants. Thus uncles, aunts, nephews, nieces, and cousins, are collaterals, or in the same collateral line: those in a higher degree, and nearer the common root, represent a kind of paternity with regard to those more remote.

Collateral, in a legal sense, is taken for any thing that hangs by the side of another, to which it relates; as a collateral assurance is that instrument which is made over and above the deed itself, for the performance of covenants between man and man; thus called as being external, and without the nature and essence of the covenant.

COLLATION, in the canon law, the giving or bestowing of a benefice on a clergyman by a bishop, who has it in his own gift or patronage. This differs from presentation; the latter being properly the act of a patron, offering the clerk to the bishop, to be instituted into a benefice, whereas the former is the act of the bishop himself. The collator can never confer a benefice on himself.

Collation, in common law, the comparision or presentation of a copy with its original, to see whether or not it is conformable; or the report or act of the officer who made the comparison. A collated act is equivalent to its original, provided all the parties concerned were present at the collation.

COLLATIONE *facta non post mortem alterius*, a writ to the justices of the common pleas, commanding them to issue their writ to the bishop, for the admitting of a clerk in the place of another presented by the king; such other clerk, during the suit between the king and the bishop's clerk, being dead.

COLLEGATORY, in the civil law, a person who has a legacy left him in common with one or more other persons. If the thing is bequeathed *in solido*, the portion of the deceased collegatory accrues to the rest.

COLLEGE, an assemblage of several bodies or societies, or of several persons into one society.

College, among the Romans, served indifferently for those employed in the offices of religion, of government, the liberal and even mechanical arts, and trades; so that, with them, the word signified what we call a corporation or company. Each of these colleges had distinct meeting-places or halls; and likewise, in imitation of the state, a treasury and common chest, a register, and one to represent them upon public occasions, and acts of government. These colleges had the privilege of manumitting slaves, of being legates, and making by-laws for their own body, provided they did not clash with those of the government.

There are various colleges on foot among the moderns, founded on the model of those of the ancients. Such are the three colleges of the empire, viz.

College *of electors*, or their deputies, assembled in the diet of Ratisbon.

College *of princes*, the body of princes, or their deputies, at the diet of Ratisbon.

College *of cities* is, in like manner, the body of deputies which the imperial cities send to the diet. See Elector, and Diet.

College *of cardinals*, or the sacred college, a body composed of the three orders of cardinals.

College is also used for a public place endowed with certain revenues, where the several branches of learning are taught. An assemblage of several of these colleges constitutes an university. In England the erection of colleges is part of the royal prerogative, and not to be done without the king's licence. The university of Oxford consists of nineteen colleges and six halls; that of Cambridge, of twelve colleges and four halls; and that of Paris, of fifty-four colleges, though, in reality, there are but ten where there is any teaching.

Colleges in the universities are generally lay corporations, although the members of the college may be all ecclesiastical. 2 Salk. 672. And in the government thereof, the king's courts cannot interfere, where a visitor is specially appointed. 1 Blacks. 483.

The two universities, in exclusion of the king's courts, enjoy the sole jurisdiction over all civil actions and suits, except where the right of freehold is concerned; and also in criminal offences or misdemeanors under the degree of treason, felony, or maim. 3 Black. 83. Their proceedings are in a summary way, according to the practice of civil law. Wood, b. 4. c. 2. But they have no jurisdiction, unless the plaintiff or defendant be a scholar or servant of the university, and resident in it at the time. An appeal lies from the chancellor's court to the congregation, thence to the convocation, and thence to the delegates.

College *of civilians*, commonly called *doctors'-commons*, founded by Dr. Harvey, dean of the arches, for the professors of the civil law residing in the city of London. The judges of the arches, admiralty, and prerogative court, with several other eminent civilians, commonly reside here. To this college belong 34 proctors, who make themselves parties for their clients, manage their causes, give licences for marriages, &c.

In the common hall of doctor's-commons are held several courts, under the jurisdiction of the civil law; par-

ticularly the high court of admiralty, the court of delegates, the arches court of Canterbury, and the prerogative court of Canterbury: whose terms for sitting are much like those at Westminster, every one of them holding several court-days; most of them fixed and known by preceding holidays, and the rest appointed at the judge's pleasure.

COLLEGE *of physicians*, a corporation of physicians in London, whose number, by charter, is not to exceed 80. The chief of them are called fellows; and the next candidates, who fill up the places of fellows as they become vacant by death or otherwise. Next to these are the honorary fellows; and lastly the licentiates, that is, such as being found capable, upon examination, are allowed to practise physic.

This college has several great privileges granted by charter and acts of parliament. No man can practise physic in or within seven miles of London, without licence of the college, under the penalty of 5*l*. Also persons practising physic in other parts of England, are to have letters testimonial from the president and three elects, unless they are graduate physicians of Oxford or Cambridge. Every member of the college is authorized to practise surgery in London or elsewhere; and that they may be able at all times to attend their patients, they are freed from all parish offices. The college is governed by a president, four censors, and twelve electors. The censors have, by charter, power to survey, govern, and arrest, all unlicensed physicians or others practising physic in or within seven miles of London; to fine, amerce, and imprison them at discretion; to search apothecaries' shops, &c. in and about London; to see if their drugs, &c. be wholesome, and the compositions according to the form prescribed by the college in their dispensaries; and to burn or otherwise destroy those that are defective or decayed, and not fit for use. They are judges of records, and not liable to action for what they do in their practise but by judicial process; subject, nevertheless, to appeal to the college of physicians. However, the college is not very rigorous in asserting its privileges, there being some of very good abilities who practise in London, &c. without their licence: yet by law, if any person not expressly allowed to practise, take upon him the cure of any disease, and the patient die under his hand, it is deemed felony in the practiser.

[A COLLEGE *of physicians* was formed in Philadelphia in the year 1787, and incorporated in the year 1789 by the legislature of Pennsylvania. The objects of the college, as stated by their constitution, are, "to advance the science of medicine, and thereby to lessen human misery, by investigating the diseases and remedies which are peculiar to this country; by observing the effects of different seasons, climates and situations upon the human body; by recording the changes which are produced in diseases, by the progress of agriculture, arts, population and manners; by searching for medicines in the American woods, waters, and in the bowels of the earth; by enlarging the avenues of knowledge from the discoveries and publications of foreign countries; and by cultivating order and uniformity in the practice of physic. (*a*)

Sion-COLLEGE, or the college of the London clergy, was formerly a religious house, next a spital or hospital, and now it is a composition of both, viz. a college for the clergy of London, who were incorporated in 1631, at the request of Dr. White, under the name of the president and fellows of Sion-college; and an hospital for ten poor men: the first within the gates of the house, and the latter without.

This college consists of a president, two deans, and four assistants, who are annually chosen from among the rectors and vicars in London, subject to the visitation of the bishop. They have one of the finest libraries in England, built and stocked by Mr. Simpson, chiefly for the clergy of the city, without excluding other students on certain terms: they have also a hall with chambers for the students, generally filled with the ministers of the neighbouring parishes.

Gresham COLLEGE, or COLLEGE *of philosophy*, a college founded by sir Thomas Gresham, who built the Royal-exchange; a moiety of the revenue whereof he gave in trust to the mayor and commonalty of London, and their successors for ever, and the other moiety to the company of mercers; the first to find four able persons to read in the college divinity, astronomy, music, and geometry; and the last three or more able men to read rhetoric, civil law, and physic; a lecture upon each subject is to be read in term-time, every day except Sundays, in Latin in the forenoon, and the same in English in the afternoon; the lecture on music is to be read alone in English. The lecturers have each 50*l*. per annum, and a lodging in the college.

COLLEGE *of heralds*, commonly called the *heralds' office*, a corporation founded by charter of king Richard the Third, who granted them several privileges; as to be free from subsidies, tolls, offices, &c. They had a second charter from king Edward the Sixth; and a house built near doctors'-commons by the earl of Derby, in the reign of king Henry the Seventh, was given them by the duke of Norfolk in the reign of queen Mary, which house is now rebuilt. This college is subordinate to the earl marshal of England. They are assistants to him in his court of chivalry, usually held in the common-hall of the college, where they sit in their rich coats of his majesty's arms.

COLLEGIATE *church*, a church built and endowed for a society, or a body corporate of a dean or other president, and secular priests, as canons or prebendaries in the same church.

[COLLEMA, in botany, a genus of lichenes order in the cryptogamia class of plants. (*a*)

COLLET, in glass-making, is that part of glass vessels which sticks to the iron instrument wherewith the metal was taken out of the melting-pot: this is afterwards used for making green glass.

COLLINSONIA, in botany, a genus of the monogynia order, in the decandria class of plants, and in the natural method ranking under the 40th order, personatæ. The corolla is unequal, with its under-lip multifid, and the segments capillary. There are two species, natives of North America, but possessed of no remarkable properties.

COLLUTHIANS, in church history, a religious sect which arose in the sixth century, on occasion of the indulgence shown to Arius by Alexander, patriarch of Alexandria; they held that God was not the author of the evils and afflictions of this life, &c.

COLLYRIDIANS, in church history, a sect of ancient heretics, who paid divine honours to the Virgin Mary, offering her little cakes called *collyrida*.

COLLYRIUM. See PHARMACY.

COLON, in anatomy, the second of the three large intestines. See ANATOMY.

COLON, in grammar, a point or character marked thus (:), showing the preceding sentence to be perfect or entire; only that some remark, farther illustration, or other matter connected therewith, is subjoined.

COLONEL, in military matters, the commander in chief of a regiment, whether horse, foot, or dragoons.

A colonel may lay any officer of his regiment in arrest, but must acquaint the general with it; he is not allowed a guard, only a sentry from the quarter guard.

COLONNADE, in architecture, a peristyle of a circular figure, or a series of columns disposed in a circle, and insulated withinside. Such is that of the little park at Versailles, consisting of 32 Ionic columns, all of solid marble, and without incrustation. A polystile colonnade is that whose number of columns is too great to be taken in by the eye at a single view. Such is the colonnade of the palace of St. Peter's at Rome, consisting of 284 columns of the Doric order, each above four feet and a half diameter, all in Tiburtine marble.

COLOPHONY. See PHARMACY.

COLOSSUS, a statue of a gigantic or enormous size. The most famous of this kind was the colossus of Rhodes, made in honour of Apollo, by Chares the disciple of Lysippus. It was 86 feet high, and its thumb so large that few people could embrace it. This statue was placed across the mouth of the harbor at Rhodes, and the ships in full sail passed betwixt its legs.

COLOUR. See OPTICS.

COLOUR, in painting, is applied both to the drugs, and to the tints produced by those drugs variously mixed and applied.

We shall in this article give a brief account of the different pigments or colours which are used either in water or oil for the purposes of drawing or painting.

Red. Lakes. This term is used to denote a species of colours formed by the combination of alumina, or the oxyd of tin, with the colouring matters of vegetables. The lakes chiefly used are red colours; and these are of different qualities, according to the basis and colouring matter employed; such as carmine, Florence-lake, and madder-lake.

Carmine is a very rich bright crimson colour, and stands well in water. For the preparation of carmine, four ounces of finely pulverized cochineal are to be poured into four or six quarts of rain or distilled water, that has been previously boiled in a pewter kettle, and boiled with it for the space of six minutes longer. Eight scruples of Roman alum, in powder, are to be then added, and the whole kept upon the fire one minute longer. As soon as the gross powder has subsided, and the decoction has become clear, it is to be carefully decanted into large cylindrical glasses covered over, and kept undisturbed till a fine powder is observed to have settled at the bottom. The liquor is then to be poured off from this powder, which is to be gradually dried. From the liquor, which is still much coloured, the rest of the colouring matter may be separated by means of the solution of tin, when it yields a carmine little inferior to the former.

Florentine lake is the kind in general use, known by the name of lake. It is used in water, and also in oil, but does not stand; which is much to be lamented, as it is a very beautiful colour, and there is no substitute that will completely answer all the purposes of lake. The best sort may be prepared from the sediment of cochineal that remains in the kettle after making carmine, adding to it a small quantity of cochineal or Brazil-wood, and precipitating the colouring matter with a solution of tin.

Madder lake is very little known as a colour. It is not so bright and rich as the last-mentioned lakes, but has this valuable advantage; that it stands much better, and may answer many of the purposes of Florence lake. It is prepared nearly in the same manner as the foregoing.

Rose-lake. This is generally called rose-pink. It is a lake made by a basis of chalk, coloured by Brazil or Campeachy wood. It does not stand, and is only used for house-painting and paper-hanging.

Vermilion, a bright scarlet pigment, formed from sulphur and quicksilver; when of a coarse kind, it is called cinnabar. Its goodness is known by its brightness, and inclining to a crimson hue. It is a very useful colour in oil, where it stands very well; but in water it is apt to turn black.

Red-lead, or minium, is lead calcined till it acquires a red colour, by exposing it with a large surface to the fire. It is also made from litharge, which is a calx or oxyd of lead; but is not so good as when made directly from metallic lead. This colour is very apt to turn black, both in water and oil, and is therefore seldom used but for very coarse purposes.

Indian-red is a very useful colour, answering some of the purposes of lake: it stands well both in water and oil. It is difficult to procure the genuine kind, which comes from the East Indies. What is sold for Indian-red is said to be chiefly made in England.

Venetian-red, is a native red-ochre, rather inclining to the scarlet than the crimson hue; it is not far different from the common Indian red, but fouler, and is chiefly used by house-painters.

Spanish-brown is also an earthy substance, found in the same state in which it is used; it is nearly of the same colour as Venetian-red, but coarser. It is used only for the commonest purposes. It does not change.

Light-red, or burnt ochre. This is common yellow-ochre, heated red-hot in the fire, till the colour changes from yellow to a red. It is a very excellent colour, both in water and oil; having the quality in common with all the ochres, of standing perfectly well.

Red-chalk. This is the same substance as is used for drawing on paper, in the manner of a crayon. It is very much like light-red, and is used instead of it for some purposes. It stands perfectly well, and may be used both in water and oil.

Burnt terra di Sienna. This colour is made by calcining raw terra di Sienna till it acquires a red colour. It is of a very rich tint, and is much used both in water and oil. It stands well in both.

Blue. Ultramarine is prepared from lapis lazuli, by

calcining and washing it very clean. When genuine, it is an extremely bright blue colour, somewhat transparent both in oil and water, and stands perfectly well. On these accounts it is of the utmost value, being excellent in every kind of painting, even in enamel; but its great price prevents the general use of it.

Ultramarine ashes. This is the residuum, after washing the lapis lazuli, in which a portion of the ultramarine still remains. It is very subject to be adulterated. It is not so bright as ultramarine; being like that colour, with a tint of red and white in it. When genuine it stands well.

Prussian-blue. This colour is iron combined with a peculiar acid, called the prussic acid. It is made in the following manner:

Two parts of purified potass are most intimately blended with three parts of dried and finely pulverized bullock's blood. The mass is first calcined in a covered crucible, and on a moderate fire, until no more smoke or flame appears; and it is after this brought to a complete yet moderate ignition: or equal parts of potass and finely-powdered coals, prepared from bones, horns, claws, &c. are mingled, and heated in a covered crucible to a moderate redness. This done, either of those two calcined masses is, after cooling, lixiviated with boiling water, and the lixivium filtred. Nothing remains now but to make a solution of one part of green vitriol and two parts of alum; and to add to it while yet hot the above lixivium, little by little however; and to separate the greenish-blue precipitate which then forms, by means of a filtre. If afterwards a slight quantity of diluted muriatic acid is affused upon this precipitate, it assumes a beautiful dark-blue colour. The operation is terminated by edulcorating and drying the pigment thus prepared. Prussian-blue is an extremely beautiful colour when properly prepared, and stands well. Common Prussian-blue is apt to contain some iron, which causes it to turn greenish or olive.

Verditer is a blue pigment, obtained by adding chalk or whitening to the solution of copper in aqua-fortis. The best sort is prepared by the refiners; who employ for this purpose the solution of copper which they obtain in the process of parting, by precipitating, silver from aqua-fortis by plates of copper. Common verditer is made from the sulphate of copper or blue, by the manufacturers in Sheffield and Birmingham. Verditer is only used for very coarse purposes, chiefly by the paper-stainers. It has been sometimes called sanders-blue, from ignorance of the meaning of the term *cendres blues*, or blue ashes, which the French call it.

Indigo. This colour is extracted from a plant that grows in the East and West Indies. It is not so bright as Prussian-blue, but it is cooler, and has the advantage of being very durable. It cannot be dissolved by water, but may by the sulphuric acid; and it then forms Scott's liquid blue, so much used for colouring silk stockings, &c.

Smalt. This is glass coloured with cobalt, and ground to a fine powder. Its coarseness prevents its being used much for painting in oil or water. It is employed sometimes by strewing it upon a ground of oil-paint. It is also used in enamel-painting. It stands well.

Bice is only smalt more finely levigated.

Yellow. Indian-yellow. This is the brightest of all yellows for water-colours, and is perfectly durable. It is said to be procured from the urine of the buffalo. In the East Indies it is a very common and cheap colour; the natives there use it commonly for colouring their calicoes, which they do without any mordant; so that the colour is washed out again when the cloth is dirty.

King's-yellow. This colour is orpiment refined; which is a substance dug out of the earth, and consists of sulphur joined to arsenic; or it may be prepared by subliming sulphur with arsenic. It is of a very bright yellow, but does not stand well; and great caution should be used in emyloying it, as it is a strong poison.

Naples-yellow. This is a very durable and bright yellow; it comes from Naples, and is supposed to be prepared from lead and antimony.

Yellow-ochre. This is an earth coloured by oxyd of iron. It is a cheap colour, and not very bright, but is valuable on account of its standing well. Roman-ochre is a superior kind of yellow-ochre.

Dutch-pink. This pigment is formed of chalk, coloured with the juice of French berries, or other vegetables affording a yellow colour. It does not stand, and is chiefly used for common purposes.

Gamboge is a gum brought from the East Indies. It readily dissolves in water, and is a fine bright yellow. It is used only in water, and is very serviceable.

Massicot is an oxyd of lead, prepared by calcining white-lead. It is very little used, the colour not being very bright.

Gall-stones. This is a concretion or hard substance, formed in the gall-bladders of beasts; or it may be obtained from the gall of animals. It is a very rich colour, but does not stand.

Raw terra di Sienna, is a native ocherous earth brought from Italy. It is a fine warm colour, and stands well.

Orange-lake is the tinging part of annotto precipitated together with the earth of alum. It does not stand.

Brown-pink is the tinging part of some vegetable substance precipitated upon the earth of alum. It is of a fine rich greenish yellow, but does not stand.

Green. There are few colours that are useful as greens; accordingly, it is the practice with artists to form their greens by the mixture of blue and yellow colours. By varying these, a vast variety of green tints may be obtained.

Sap-green is the concreted juice of the buckthorn berries. It is never used in oil. It is employed chiefly in flower-painting and colouring prints, &c.

Verdigris. If plates of copper, moistened from time to time with vinegar, are left exposed to the air, they will be converted into a green oxyd, called verdigris: this is an imperfect oxyd of copper, combined with a small portion of acetic acid, carbonic acid, and water. It is prepared in large quantities, chiefly in France near Montpellier, by stratifying copper-plates with the husks of grapes yet under vinous fermentation, which soon grow acid, and corrode the copper. After the plates have stood in this situation for a sufficient time, they are moistened with water, and exposed in heaps to the air. The verdigris is scraped off from their surface as it forms.

Verdigris is of a blueish-green colour, but has no body, and does not stand. It is only used for very coarse purposes. It answers best when used in varnishes.

Distilled verdigris, sometimes called crystals of verdigris, is prepared from common verdigris, by dissolving it in vinegar. It is of a very bright green; and is used chiefly for varnishes, and in colouring maps, &c.

Brown colours. Bistre is the finer part extracted from the soot of burnt wood. It is much used alone for sketches in water colours, being a transparent warm colour. There is an excellent sort prepared in Ireland.

Cologne-earth is a mineral substance of a blackish brown colour. It is a very useful colour; though what is generally sold in the shops for Cologne-earth, is an artificial mixture of several colours.

Raw-umbre is a native ochreous earth, of a light brown. It stands well.

Burnt-umbre is only the last-mentioned colour calcined in the fire. It then acquires a rich deep brown, and is of great use, being a fine colour, and standing perfectly well.

Asphaltum is used in oil, and is a very rich deep brown. It is a transparent or glazing colour. It will not work in water; but when dissolved in turpentine, it becomes a useful substance for giving deep and spirited touches to drawings.

White. Flake-white is an oxyd of lead, formed by corroding lead with vegetable acids or vinegar.

White-lead is the same colour as flake-white, only of an inferior quality. It is the only white used in oil painting, and is a very useful colour; but in water it always turns black, and should never be used.

Pure carbonate of lime is very useful as a white in water-colours, as it stands perfectly well.

Egg-shell white, and oyster-shell white, are only egg-shells or oyster-shells calcined, by which the animal gluten is destroyed, leaving the lime behind, which soon attracts the carbonic acid again from the atmosphere. Well-washed Spanish-white, or common whitening, answers the same purpose.

Black. Lamp-black is the soot of oil, collected after it is formed by burning. It is very generally used, both in oil and water, and stands perfectly well.

Ivory-black is the coal of ivory or bone, formed by giving them a great heat, while they are deprived of all access of air. It is of a more intense black than lamp-black.

Blue-black is the coal from burning vine-stalks in a close vessel. It is like ivory-black, with a tint of blue.

Colour, in dyeing. See Dyeing.

Colour, in heraldry. The colours generally used in heraldry are red, blue, black, green, and purple; which the heralds call gules, azure, sable, vert or sinople, and purpure; tenne or tawny, and sanguine, are not so common: as to yellow and white, called or and argent, they are metals, not colours.

Colour, in law, some probable plea, though really false in itself, and only calculated to draw the trial of the cause from the jury to the judge; for which reason it ought to be matter in law or doubtful to the jurors.

Colour *of office*, signifies some unjust action done under countenance of an office, and is opposed to *virtute officii*, which implies a man's doing a right and just thing in the execution of his office.

Colours, in the Latin and Greek churches, are used to distinguish several mysteries and feasts.

To Colour *strangers' goods*, in commerce, is when a freeman allows a foreigner to enter goods at the custom-house in his name.

COLOURING, in painting, is the art of applying and disposing various colours in such a manner as to be productive either of an imitation of the natural hues of the objects represented, of harmonious arrangement of tints, or of force and brightness of effect. See Painting.

COLUBER, a genus of serpents. The generic character is, scuta or undivided lamellæ under the abdomen, broad alternate scales under the tail. This is by far the most numerous of all the Linnæan genera of serpents: and the species differ greatly in size and habit, according to their respective tribes; some, as the vipers, having large, flattish, and subcordate heads, with rather short than long bodies and tails; while others, as the major part of the harmless serpents, have, in general, small heads, with longer bodies and tails in proportion. In some few species, exclusive of the usual subcaudal scales, are a few scuta or undivided lamellæ, either at the beginning or towards the tip of the tail. It is to be observed, that in the investigation of this genus the subcaudal scales, though alternate, are reckoned by pairs, so that the number marked under the respective species is always to be understood to mean so many pairs. There are ninety-seven species: the following are the most remarkable.

1. Coluber Berus, or common viper, (See Plate XXXVI. Nat. Hist. fig. 136), which appears to be pretty generally diffused over the whole ancient continent, and which is by no means uncommon in England, has been known from times of remote antiquity, though all the particulars relative to its nature and manners are even yet not fully understood.

The general length of the viper is about a foot and half, or two feet, though some have been seen of much greater length, measuring near three feet: the fangs are situated, as in other poisonous serpents, on each side the fore part of the upper jaw; and are generally two in number, with a few smaller ones lying near the principal or large fangs, as if intended by nature to supply the place of the former, when lost either by age or accident.

The viper has always been considered as the most poisonous of the European serpents, and innumerable are the cases recorded by medical and other writers of the fatality of its bite; yet the instances seem to be far less frequent than generally supposed; and though the bite of this animal produces a painful and troublesome swelling, yet it is rarely of any other bad consequence. No doubt the cases must differ, as in the bite of every other poisonous serpent, according to the nature of the part bitten, the constitution of the person, the strength and vigour of the animal, the season of the year, &c. and if the bite happens directly on a vein, it may perhaps be productive of the most alarming symptoms, and even sometimes prove fatal: yet Fontana, even in the warm climate of Italy, seems to doubt whether any well-attested instance could be adduced in which the viper had killed any person by its bite. The poison of the

viper was in ancient times collected by barbarian nations as a poison for their arrows; the Scythians, according to Pliny, using it for that purpose mixed with human blood: the poison of other serpents is used in a similar manner by savage nations at the present day.

The most established application for the bite of a viper is the common olive-oil, thoroughly rubbed on the wounded part, and about a wine-glassful taken internally: this the viper-catchers use, as is pretended, with perfect success; and all other applications, as volatile alkali, &c. seem of far less certain efficacy.

The viper, though so much dreaded on account of its bite, has been very highly esteemed, both by the ancients and moderns, in a medical view, and used as a restorative and strengthening diet. This idea seems to have originated from the animal's casting its skin, like other snakes, and thus appearing, as it were, in a state of renovated youth; and the snakes being made the emblem of health, and consecrated to Æsculapius, must have depended on the same idea. We are indeed of opinion, that it is possible (could we overcome our reluctance to it,) that viper's flesh might prove nutritious food, but that to ascribe any medical virtues to it is a vulgar error.

The viper is viviparous, producing its young towards the close of the summer. "On the 4th of August, 1733," says Mr. White, "we surprised a large female viper, which seemed very heavy and bloated, as it lay on the grass, basking in the sun. When we came to cut it up, we found that the abdomen was crowded with young, fifteen in number; the shortest of which measured full seven inches, and were about the size of full grown earthworms. This little fry issued into the world with the true viper-spirit about them, showing great alertness as soon as disengaged from the belly of the dam: they twisted and wriggled about, and set themselves up, and gaped very wide when touched with a stick, showing manifest tokens of menace and defiance; though as yet they had no manner of fangs that we could find, even with the help of our glasses." Mr. White, in another part of his work, informs us, that in the month of May a female viper was opened, which had in it a chain of eleven eggs, about the size of those of a blackbird; but not so far advanced as to show the rudiments of the young.

"Several intelligent persons," adds Mr. White, "assure me that they have seen the viper open her mouth, and admit her helpless young down her throat on sudden surprises, just as the opossum does her brood into the pouch under her belly upon the like emergencies; and yet the London viper-catchers insist on it to Mr. Barrington that no such thing ever happens.

Sir Thomas Brown, however, seems inclined to believe this circumstance. The young, says he, supposed to break through the belly of the dam, will upon any fright, for protection, run into it; for then the old one receives them in at her mouth: the fright being past, they will return again, which is a peculiar way of refuge, and although it seem strange, it is avowed by frequent experience and undeniable testimony.

There is a variety of this species entirely black.

2. The cerastes or horned viper, which commonly grows to the length of about a foot or fifteen inches, and sometimes to a larger size, is distinguished by a pair of horns or curved processes, situated above the eyes, and pointing forwards: these horns have nothing analogous in their structure to the horns of quadrupeds, and are by no means to be considered in the light of either offensive or defensive weapons: they increase, however, the natural antipathy so generally felt against the serpent tribe, and give the animal a more than ordinary appearance of malignity. The cerastes is a native of many parts of Africa, and is principally found in sandy deserts and dry places. Its usual colour is a pale yellowish or reddish brown, with a few rather large, distant, round, or transversely oblong spots of a deeper colour, dispersed along the upper parts of the body, the belly or under part being of a pale lead-colour. In Syria and Arabia the cerastes is particularly frequent, and is also found in many parts of Egypt, &c. It bears a very great affinity to the common viper, and its bite is perhaps still more to be dreaded; since, exclusive of the general danger of treading accidentally on this reptile, and thus irritating it unawares, it is said to possess a propensity of springing with great suddenness to a considerable distance, and assailing without provocation those who happen to approach it.

The celebrated Abyssinian traveller, Mr. Bruce, is of opinion that this was the aspic employed by Cleopatra to procure her death. He adds some incredible stories respecting the power of certain persons in Africa to charm these and other serpents so as to prevent their biting them. If these narratives have any foundation, the animals must in some way have been previous disarmed of their fangs, as the cobra de capello is by the Indian jugglers.

3. Coluber nasicornis, or horn-nose snake, adds to the number of those malignant reptiles whose bite, in the hotter regions of the globe, proves the dreadful forerunner of a speedy and painful death. If at the first glance of most of the serpent tribe an involuntary sort of horror and alarm is so often felt by those who are unaccustomed to the examination of these animals, how much greater dread must the unexpected view of the species here exhibited be supposed to inflict! when to the general form of the creature are superadded the peculiar fierceness and forbidding torvity with which nature has marked its countenance; distinguished by the very uncommon appearance of two large and sharp-pointed horns, situated, not as in the cerastes, above the eyes, but on the top of the nose or anterior part of the upper jaw. These horns stand nearly upright, but incline slightly backwards and a little outwards on each side, and are of a substance not absolutely horny, but in some degree flexible: their shape is somewhat triangular or three-sided; they are about half an inch in length, and at the fore-part of the base of each stands an upright strong scale, of nearly the same shape with the horn itself, and thus giving the appearance of a much smaller pair of horns. The mouth is furnished with extremely large and long fangs or tubular teeth, situated as in other poisonous serpents, and capable of inflicting the most severe wounds: two of these fangs appear on each side of the mouth, the hinder pair being smaller than the others. The length of this animal is about thirty-five inches. Its colour is a yellowish olive-brown, very thickly sprinkled all over with minute blackish specks: along the whole length of the back is placed a series of yellowish-

brown oblong spots or marks, each of which is imbedded in a patch of black; and on each side of the body, from head to tail, runs an acutely-flexuous or zigzag line or narrow band of an ochre-colour: the horn-nose snake is supposed to be a native of the interior parts of Africa.

4. The coluber naja, or cobra de capello, (See Plate XXXVI. Nat. Hist. fig. 138.) is a native of India, where it appears to be one of the most common, as well as most noxious, of the serpent tribe; very frequently proving fatal, in the space of a few minutes, to those who unfortunately experience its bite. Its remarkable form and colours are such as to distinguish it with great ease from almost every other snake. Its general length seems to be three or four feet, and the diameter of the body about an inch and a quarter. It has obtained its Portuguese title of cobra de capello, or hooded snake, from the appearance which it presents when viewed in front in an irritated state, or when preparing to bite; at which time it bends the head rather downwards, and seems hooded in some degree by the expanded skin of the neck. In India it is every where exhibited publicly as a show, and is, of course, more universally known in that country than almost any other of the race of reptiles. It is carried about in a covered basket, and so managed by its proprietors as to assume, when exhibited, a kind of dancing motion; raising itself up on its lower part, and alternately moving its head and body from side to side for some minutes, to the sound of some musical instrument which is played during the time. The Indian jugglers, who thus exhibit the animal, first deprive it of its fangs, by which means they are secured from the danger of its bite.

Dr. Russel, in his account of experiments made in India with this serpent, observes, that, as a general standard for a comparison of the effect of its bite with that of other poisonous serpents, he never knew it prove mortal to a dog in less than twenty-seven minutes, and to a chicken in less than half a minute. Thus, fatal as it is, its poison seems not so speedy in operation as that of the rattle-snake, which has been known to kill a dog in the space of two minutes.

5. The coluber aquaticus, or water viper, is called in Carolina the water rattle-snake; not that it has a rattle; but is a large snake, and coloured not much unlike the rattle-snake, and the bite is said to be as mortal. This snake frequents the water, and is never seen at any great distance from it: the back and head are brown; the belly transversely marked with black and yellow alternately, as are the sides of the neck: the neck is small, the head large, and armed with the like destructive weapons as the rattle-snake: it is very nimble, and particularly dextrous in catching fish. In summer great numbers are seen lying on the branches of trees hanging over rivers, from which at the approach of a boat they drop down into the water, and often into the boat on the men's heads: they lie in this manner to surprise either birds or fish, after which last they plunge, and pursue them with great swiftness, and catch some of a large size, which they carry on shore and swallow whole. The tail is small towards the end, and terminates in a blunt horny point about half an inch in length, and which, though harmless, is considered as of dreadful efficacy by the credulous vulgar, who believe that the animal is able, with this weapon, not only to kill men and other animals, but even to destroy a tree by wounding it with it; the tree withering, turning black, and dying.

6. Coluber argus, or argus snake, (See Plate XXXVI. Nat. Hist. fig. 135.) is a large and elegant species, measuring, according to Seba, above five feet in length, and being of a moderate thickness in proportion: the head is large, flattish, covered in front with small scales, and so very protuberant on each side at the hind part as to appear heart-shaped, or rather bilobate: the teeth large and strong: the whole upper surface of the animal is of a dusky chesnut colour, the scales being small, ovate, and each marked by a white speck; while the body is beautifully marked from head to tail by numerous transverse rows of round read spots; the tail is moderately slender, tapering to a point, and seemingly measuring about a fifth of the whole length. This snake is, according to Seba, a native of Arabia. The appearance of the head seems strongly to indicate a poisonous species.

7. The coluber natrix, or ringed snake (See Plate XXXVI. Nat. Hist. fig. 137.) appears to be pretty generally diffused throughout all parts of Europe, frequenting woods, moist hedges, and shady places; in colour it occasionally varies, but is generally either of a blueish grey or pale olive on the upper parts, marked along the sides by a row of small transverse black streaks, alternating with some smaller spots of the same colour; and on each side the neck is a black and somewhat semilunar patch, the horns or tips pointing forward: this is bounded in front by a second patch of a pale yellow or whitish colour, thus forming a kind of collar on each side the neck. This animal is of an innoxious nature, and may be tamed to a considerable degree. Mr. White, in his History of Selborne, has the following remark on this subject: "I knew a gentleman who kept a tame snake, which was in its person as sweet as any animal; but as soon as a stranger, or a dog or cat, came in, it fell to hissing, and filled the room with such nauseous effluvia as rendered it hardly supportable." The snake chiefly lives by preying on frogs, mice, small birds, insects, worms, &c. It is known to frequent the water occasionally, for the sake of frogs, &c. and is capable of swimming, though not with any great degree of celerity. It deposits its eggs in any warm and moist situation, as under hedges, in dunghills, &c. in the form of a continued chain or necklace of ova, to the number of twelve, fourteen, sixteen, or even twenty, of the size of those of a blackbird, and of a whitish colour: these, according to the observations of Mr. White, do not hatch till the spring following.

During the winter the snake conceals itself in any convenient retreat, and becomes nearly torpid, re-appearing in the spring, when it casts its skin, which cracking or opening on the edges of the lips, is, by the efforts of the animal, gradually thrown off, in an inverted direction, throughout its whole length, to the very terminal scale of the tail; and so complete is the spoil or exuvium, as to exhibit the very coat or membrane of the eyes themselves: the whole skin is entirely transparent.

8. The coluber atrovirens, or French snake, is an animal of a perfectly harmless nature, and, like the former, is capable of being tamed to a considerable degree. The count de Cepede relates, from Mr. Bomare, an anecdote

relative to a snake which he supposes to have been of this species, which had been so completely tamed by a lady, as to come to her whenever she called it, follow her in her walks, wreathe itself round her arms, and sleep in her bosom. One day, when this lady went in a boat, to some distance up a large river, she threw the snake into the water, imagining that it would readily recover the boat by swimming; but the current proving unusually strong, at that juncture, owing to the advance of the tide, the poor animal, in spite of all its efforts to reach the vessel, was unfortunately drowned.

9. The coluber constrictor, or black snake, is a large and very long snake: some being six feet in length: they are all over of a shining black, never changing their colour; and are very nimble and beneficial in killing rats, which they pursue with wonderful agility to the roofs and all parts of houses and barns, where rats are able to run, for which service they are preserved by most of the inhabitants: they are bold and furious, leaping at and biting those that attack them, though no harm ensues; their bite not being venomous: it is commonly said in Carolina that they will attack and swallow rattle-snakes: it is certain that most or all snakes will devour one another, not only of their own but of other kinds. They are the most numerous of all snakes in North America.

"Many ridiculous frights," says Mr. Pennant, "have happened from this innocent reptile. As every one in America is full of the dread of the rattle-snake, they are apt to fly at the sight of any of the serpent kind. This pussues, soon overtakes, and twisting round the legs of the fugitive, soon brings him to the ground; but he happily receives no hurt, but what may result from the fright; all the mischief this species does is to the housewives, for it will skim their milk-pans of the cream, and rob their hen-roosts of all the eggs."

10. The coluber austriacus, or smooth snake, is found in France and several other parts of Europe, It inhabits moist meadows, hedges, watery places, &c. It is of a fierce disposition in its wild state, biting with much eagerness such animals as happen to attack it; but is incapable of producing any injury, being unprovided with poisonous fangs, and is easily tamed, in which state it shows a considerable degree of attachment. It occasionally varies somewhat in colour, the upper parts having a strong tinge of rufous, and the abdomen of dusky brown or even blackish, while the sides have a cast of yellow or green.

11. The coluber gemmatus, or bugle snake, is a beautiful species: length about fifteen or sixteen inches, colour of the upper parts blue, with three narrow equidistant stripes from head to tail; the two lateral stripes being white, the middle one black, marked by a row of small white specks alternately oblong and round, representing a small string of beads and bugles: head large-scaled, and marked on each side by three or four spots forming a band across the eyes, the top spotted with pale blue marks bordered with black: the abdomen is white, each scutum being marked at its edge, near the body, with a small black speck, forming two rows down the abdomen: native country unknown: described by Cepede from a specimen in the royal cabinet.

12. The coluber mycterizans, or longsnouted snake, is in colour grass-green, with a yellow line on each side the abdomen: habit remarkably slender, measuring about three feet and a half in length, and about half an inch in diameter: head moderately large, long, and very sharp-snouted, the upper jaw running far beyond the lower: sometimes this species varies in having an additional pair of yellow abdominal lines, running down the middle of that part: it is an innoxious snake, though erroneously marked as poisonous in the Systema Naturæ, owing to the fanglike appearance of its large and long teeth in the upper jaw. It is a native of many parts of North America, where it is principally seen on trees, moving with great velocity in pursuit of insects, on which it is said principally to feed.

13. The coluber ahætulla, or iridescent snake, is one of the most beautiful of the whole serpent tribe (See Plate XXXVI. Nat. Hist. fig. 134;) and in general, easily distinguished by its blue-green gilded tinge, accompanied by iridescent hues: its habit is long and slender, measuring about three feet and a half, or four feet, in length, and about half or three quarters of an inch in diameter: the skin, between the scales, is blackish, and in some parts gives an additional beauty to the general colour: across the cheeks, passing through the eyes, is a jet-black streak: the head is covered above with large scales, and the snout is slightly elongated, but by no means pointed: the abdomen is pale and flattish, as in the mycterizans and some others of this tribe, and the tail is angular, thin, and of very considerable length. This species is entirely innocent, and is a native of several parts of India.

COLUBRINUM LIGNUM, snake-wood. See MATERIA MEDICA.

COLUMBA, in ornithology, the pigeon, a genus belonging to the order of passeres. The characters of this genus are as follow: the bill is straight towards the point; the nostrils are oblong, and half-covered over with a soft tumid membrane; and the tongue is entire, that is, not cloven. There are about 70 species, natives of different countries. The following are the most remarkable:

1. Columbia coronata, or great crowned pigeon, a very large species, about the size of a turkey. The bill is black, and two inches long; the irides are red; the head, neck, breast, belly, sides, thighs, and under tail-coverts, cinereous blue; the head is crested; the sex of a deep ash-colour. This species inhabits the Moluccа isles and New Guinea, and has been brought to England alive. In size it far exceeds any of the pigeon tribe; but its form and manners tell us it can belong to no other. Its note is cooing and plaintive, like that of other pigeons, only louder in proportion. The mournful notes of these birds alarmed the crew of Bougainville much, when in the neighbourhood of them, thinking they were the cries of the human species. In France they were never observed to lay eggs, nor in Holland, though they were kept for some time.

2. Columba malaccensis, the Malacca pigeon described by Sonnerat, is little larger than the house-sparrow. It is a most beautiful species, and the flesh is said to be extremely delicate. It has been transported into the Isle of France, where it has multiplied exceedingly.

3. Columba migratoria, or pigeon of passage, is about the size of an English wood-pigeon; the bill black: it is red; the head of a dusky blue; the breast and belly of a

faint red; above the shoulder of the wing there is a patch of feathers shining like gold; the wing is coloured like the head, having some few spots of black; the tail is very long, and covered with a black feather, under which the rest are white; the legs and feet are red. They come in prodigious numbers from the north, to winter in Virginia and Carolina. In these countries they roost upon one another's backs in such numbers that they often break down the limbs of oaks which support them, and leave their dung some inches thick below the trees. In Virginia Mr. Catesby has seen them fly in such continued trains for three days successively, that they were not lost sight of for the least interval of time, but somewhere in the air they were seen continuing their flight southward. They breed in rocks by the sides of rivers and lakes far north of St. Laurence. They fly to the south only in hard winters, and are never known to return.

4. Columba œnas, or the domestic pigeon, and all its beautiful varieties, derive their origin from one species, the stock dove; the English name implying its being the stock or stem, whence the other domestic birds have sprung. These birds, as Varro observes, take their Latin name, columba, from their voice or cooing: and, had he known it, he might have added the British also; for k'lommen, kylabmano, kulm, and kolm, signify the same bird. They were, and still are, to be found in most parts of England in a state of nature; but probably the Romans first taught the Britons how to construct pigeon-houses, and make birds domestic. The characters of the domestic pigeon are these. It is of a deep blueish ash-colour; the breast dashed with a fine changeable green and purple; it weighs fourteen ounces. In the wild state it breeds in holds of rocks and hollows of trees; for which reason some style it columba cavernalis, in opposition to the ring dove, which makes its nest on the boughs of trees. Nature always preserves some agreement in the manners, characters, and colours, of birds reclaimed from the wild state. This species of pigeon soon takes to build in artificial cavities, and from the temptation of a ready provision becomes easily domesticated. Multitudes of these wild birds migrate into the south of England; and, while the beech-woods were suffered to cover large tracts of ground, they used to haunt them in myriads, reaching a mile in length, as they went out in the morning to feed. They visit Britain the latest of any bird of passage, not appearing till November, and retiring in the spring. Mr. Pennant imagines, that their summer haunts are in Sweden, as Mr. Eckmark makes their retreat thence coincide with their arrival in Britain. Numbers of them, however, breed in cliffs on the coast of Wales, and of the Hebrides. The varieties produced from the domestic breed are numerous, and extremely elegant; they are distinguished by names expressive of their several properties, as tumblers, carriers, jacobines, croppers, pouters, runts, turbites, owls, nuns, &c. The most celebrated of these is the carrier. They are gregarious; lay only two eggs, and breed many times in the year. So quick is their increase, that the author of the Economy of Nature observes, that in the space of four years 14760 pigeons may come from a single pair. The male and female sit, and also feed their young, by turns: they cast provision out of their craw into the young one's mouth; they drink, not by sipping, but by continued draughts like quadrupeds.

5. Columba palumbus, the ring-dove or wood-pigeon, is a native of Europe and Asia. It is the largest pigeon we have, and might be distinguished from all others by its size alone. Its weight is about twenty ounces; its length 18, the breadth 30, inches. The head, back, and covers of the wings, are of a blueish ash-colour: the lower side of the neck and breast are of a purplish red, dashed with ash-colour; on the hind part of the neck is a semicircular line of white; above and beneath that, the feathers are glossy, and of changeable colours. This species forms its nest of a few dry sticks in the boughs of trees. Attempts have been made to domesticate them by hatching their eggs under the common pigeon in dove-houses; but as soon as they could fly, they always took to their proper haunts. In the beginning of winter they assemble in great flocks, and leave off cooing, which they begin in March, when they pair.

6. Columba passerina, or the ground-dove of Carolina, is about the size of a lark. The bill is yellow, and black at the end; the iris red; the breast and whole front of a changeable purple, with dark purple spots; the legs and feet of a dirty yellow; but the whole bird has such a composition of colours in it, that a very particular description is impossible. They fly in great numbers together, and make short flights from place to place, generally lighting on the ground.

7. Columba turtur, or turtle-dove, is a native of India. The length is twelve inches and a half: its breadth twenty-one; the weight four ounces. The irides are of a fine yellow, and the eye-lids encompassed with a beautiful crimson circle. The chin and forehead are whitish; the top of the head ash-coloured, mixed with olive. On each side of the neck is a spot of black feathers prettily tipt with white: the back ash-coloured, bordered with olive-brown: the scapulars and coverts of a reddish brown spotted with black: the breast of a light purplish red, having the verge of each feather yellow; the belly white. In the breeding season these birds are found in Buckinghamshire, and in several parts of the west of England. They are very shy, and breed in thick woods, generally of oak; in autumn they migrate into other countries. See Pl. N. H. fig. 139.

COLUMN, in the military art, a long deep file of troops or baggage. The first and second lines of the army as they are encamped, make generally two columns on a march, filing off either from the right or left: sometimes the army marches in four, six, or eight columns, according as the ground will allow: and each column is led by a general officer.

COLUMN. See ARCHITECTURE.

COLUMNA. See ANATOMY.

COLUMNEA, a genus of the angiospermia order, in the didynamia class of plants; and in the natural method ranking under the 40th order, personatæ. The calyx is quinquepartite; the upper lip of the corolla arched and entire; gibbous above the base; the antheræ converted; the capsule bilocular. There are six species, natives of the East and West Indies.

COLURES, in astronomy and geography, two great circles supposed to intersect each other at right angles

in the poles of the world, and to pass through the solstitial and equinoctial points of the ecliptic. See GEOGRAPHY.

COLUTEA, bastard-sena: a genus of the decandria order, in the diadelphia class of plants; and in the natural method ranking under the 32d order, papilionaceæ. The calyx is quinquefid; the legumen inflated, opening at the upper part of the base. There are nine species, deciduous flowering shrubs, adorned with many-lobed leaves, and butterfly-shaped flowers, of a deep yellow or red colour. They are propagated both by seeds and layers, and are hardy enough, though they sometimes require a little shelter when the weather is very cold.

COLYMBUS, DIVER, in ornithology, a genus of anseres. The bill has no teeth, is subulated, straight, and sharp-pointed; the teeth are in the throat; the nostrils are linear, and at the base of the bill; and the legs are unfit for walking. This genus includes several species, viz. the divers, guillemots, and grebes; of which the following are the most remarkable.

1. The grylle, or black guillemot, is in length fourteen inches, in breadth twenty-two; the bill is an inch and an half long, straight, slender, and black; the inside of the mouth red; on each wing is a large bed of white, which in young birds is spotted; except those in which the whole plumage is black, the legs are red. These birds are found on the Bass isle in Scotland; in the island of St. Kilda; and, as Mr. Ray imagines, in the Farn islands off the coast of Northumberland. They have also been seen on the rocks of Llandidno, in Caernarvonshire, in Wales. Except in breeding-time, the grylle keeps always at sea; and is very difficult to be shot, diving at the flash of the pan. The Welsh call this bird cascan longur, or "the sailor's hatred," from a notion that its appearance forebodes a storm.

2. The troile, or foolish guillemont, weighs 24 ounces; its length is 17 inches, the breadth 27½; the bill is three inches long, black, straight, and sharp-pointed; the inside of the mouth yellow; the feathers on the upper part of the bill are short and soft like velvet; from the eye to the hind part of the head is a small division of the feathers: the rest is of a deep mouse colour. The chief places they are known to breed in are the uninhabited isle of Priestholm, near the isle of Anglesey; on a rock called Godreve, not far from St. Ives in Cornwall; the Farn isles, near the coast of Northumberland; and the cliffs about Scarborough in Yorkshire. They are also found in most of the northern parts of Europe.

3. The septentrionalis, or red-throated diver, is more elegantly shaped than the others. It weighs three pounds. The length to the end of the tail is two feet; to the toes two feet four inches, the breadth three feet five inches. This species breeds in the northern parts of Scotland, on the borders of the lakes. It is found also in Russia, Siberia, and Kamtschatka; but does not haunt the inland lakes.

4. The glacialis, or northern diver, is three feet five inches in length; the breadth four feet eight; the bill to the corners of the mouth four inches long, black, and strongly made. This species inhabits several parts of the north of Europe, but is not very frequent on our shores, nor ever seen southward except in very severe winters. It is seldom met with on land, being for the most part on the open sea, where it is continually diving for fish, which it does with great agility, and flies high and well. It is common in Iceland and Greenland, where it breeds, and at that time frequents the fresh waters. It is sufficiently plentiful in Norway, and all along the arctic coasts, as far as the River Ob, in the Russian dominions. The natives of Greenland use the skins for clothing; and the Indians about Hudson's-bay adorn their heads with circlets of their feathers. At the last place it is known by the name of athinue-moqua. As they are seldom seen on the sea-coasts, but chiefly among the lakes, they are called by the Indians inland loons.

5. The immer, or ember-goose, is superior in size to a common goose. The head is dusky; the back, coverts of the wings, and tail, clouded with lighter and darker shades of the same. The under side of the neck spotted with dusky; the breast and belly silvery; the legs black. They inhabit the seas about the Orkney islands; but in severe winters visit the southern parts of Great Britain. They are found also in Iceland, and most parts of northern Europe; likewise in Kamtschatka; but not in any part of Siberia or Russia. It likewise inhabits Switzerland, particularly on the lake of Constance, where it is known by the name of fluder. It is said to dive wonderfully well, and to rise to an amazing distance from the place where it plunged. The female makes its nest among the reeds and flags, and places it in the water; so that it is continually wet, as in some of the grebe genus. It is difficult to be taken, either on land or swimming on the water; but is not unfrequently caught under the water by a hook baited with a small fish, its usual food.

6. The Chinese diver, supposed to inhabit China. From the various and uncertain accounts of authors, we are not clear what birds the Chinese use for catching fish: the custom, however, of doing it, is manifest, from the relations of many travellers. The bird used for this purpose has a ring fastened round the middle of the neck, in order to prevent its swallowing: besides this it has a slender long string fastened to it; and, thus accoutred, is taken by its master into his fishing-boat, from the edge of which it is taught to plunge after the fish as they pass by.

7. The cristatus, crested diver, or cargoose, weighs two pounds and a half. Its length is 21 inches, the breadth 30; the bill is two inches and a quarter long, red at the base, and black at the point. The cheeks and throat are surrounded with a long pendant ruff, of a bright tawny colour, edged with black; the chin is white; the breast and belly are of a most beautiful silvery-white, glossy as satin; the outside of the legs and the bottom of the feet are dusky; the inside of the legs and the toes of a pale green. These birds frequent the meres of Shropshire and Cheshire, where they breed; and the great fen of Lincolnshire, where they are called gaunts.

8. The urinator, or tippet-grebe, is thought by Mr. Latham not to be a different species from the former, being only somewhat less, and wanting the crest and ruff. The sides of the neck are striped downwards from the head with narrow lines of black and white; in other respects the colours and marks agree with that bird. This species has been shot on Bostern-mere in Cheshire. It is rather scarce in England, but is common in the winter time on the lake of Geneva. They appear there

in flocks of ten or twelve; and are killed for the sake of their beautiful skins. The under side of them, being dressed with the feathers on, is made into muffs and tippets; each bird sells for about fourteen shillings.

9. The horned grebe is about the size of a teal; weight, one pound; length, one foot; breadth, sixteen inches. It inhabits Hudson's-bay; and first appears in May, about the fresh waters. It lays from two to four white eggs in June, among the aquatic plants; and it is said to cover them when abroad. It retires south in autumn; and appears then at New York, staying till spring, when it returns to the north. For its vast quickness in diving it is called the water-witch. At Hudson's bay, this bird is mostly known by the name of seekeep.

COMA. See MEDICINE.

COMA BERENICES, Berenice's hair, in astronomy, a constellation of the northern hemisphere, composed of stars near the lion's tail. See ASTRONOMY.

COMARUM, marsh-cinquefoil; a genus of the polygynia order, in the icosandria class of plants, and in the natural method ranking under the 35th order, senticosæ. The calyx is decemfid; the petals five, less than the calyx; the receptacle of the seeds ovate, spongy, and persisting. There is but one species, a native of Britain. It rises about two feet high, and bears fruit somewhat like that of the strawberry.

COMB, an instrument to clean, untangle, and dress, flax, wool, hair, &c. Combs for wool are prohibited to be imported into Britain.

COMB, in a ship, a little piece of timber set under the lower part of the beakhead, near the middle. It has two holes in it, and supplies to the fore-tacks what the chesttrees do to the maintacks; that is, to bring the foretacks abroad.

COMB-MAKING. Combs are generally made of the horns of bullocks, or of elephant's and sea-horse's teeth; some are made of tortoise-shell, and others of box or holly-woods. Bullock's horns are thus prepared in order to manufacture combs. The tips are first sawn off; they are then held in the flame of a wood fire: this is called roasting, by which they become nearly as soft as leather. While in that state they are slit open on one side, and pressed in a machine between two iron plates; they are then plunged into a trough of water, from which they come out hard and flat. The comb-maker next saws them into lengths according to the sized combs he wants. To cut the teeth, each piece is fixed in a tool called a clam. The teeth are cut with a fine saw, or rather a pair of saws, and they are finished with a file.

The process used for making ivory combs is nearly the same as that already described, except that the ivory is first sawed into thin slices. About eight years ago Mr. Bundy, of Camden-town, obtained a patent for cutting combs by means of machinery. It will be thought a very singular circumstance, that before this period no method was practised in this country for cutting the teeth of combs, but that in which a pair of saws, rudely fastened in a wooden back, were directed by the human hand. With these implements, however, it is, that the very delicate superfine ivory combs, containing from 50 to 60 teeth in an inch, were manufactured.

By Mr. Bundy's machine the business of comb-making is greatly expedited; the teeth of two combs may be cut in about three minutes. The combs are afterwards pointed by applying them to an arbor or axis clothed with cutters having chamfered edges and teeth.

Tortoise-shell combs are very much used, and there are methods of staining horn so as to imitate tortoise-shell; of which the following is one: The horn to be dyed must be first pressed into a flat form, and then spread over with a paste made of two parts of quick-lime and one of litharge, brought into a proper consistence with soap-ley. This paste must be put over all the parts of the horn, except such as are proper to be left transparent, to give it a nearer resemblance to tortoise-shell. The horn must remain in this state till the paste is quite dry, when it is to be brushed off. It requires taste and judgment to dispose the paste in such a manner as to form a variety of transparent parts, of different magnitudes and figures, to look like nature. Some parts should also be semi-transparent; which may be effected by mixing whiting with a part of the paste, to weaken its operation in particular places: by this means spots of a reddish brown will be produced so as greatly to increase the beauty of the work. Horn thus dyed is manufactured into combs, and these are frequently sold for real tortoise-shell.

COMBATANT, in heraldry, a term for two beasts, as lions, &c. borne in a coat of arms in a fighting posture, with their faces to each other.

COMBINATION, in chemistry, the union of bodies of different natures from which a new compound body results. Thus an acid unites with an alkali, and it is said there is a combination betwixt these two salts, because from the union a neutral salt results. Again, metals unite with oxygen, and form a combination of the metallic oxides. Whether there exists a reciprocal affinity between every species of the particles of bodies, is a point which cannot easily be determined, though it is certainly very probable that there does. But as the particles of bodies are usually found cohering together in masses, it is evident that no heterogeneous bodies can combine unless their affinity for each other be stronger than the cohesive force which unites the respective particles of each. Now whenever two bodies constantly refuse to combine, in whatever situation we place them, we say that they have no affinity for each other; meaning merely that their affinity is not so great as to produce combination. Thus we say that there is no affinity between oil and water, because these two liquids refuse to combine together; yet when oil is united with alkali, and in the state of soap, it dissolves in water; a proof that there does exist an affinity between water and oil, though not strong enough to produce combination. We say also, that there is no affinity between azote and lime, because azotic gas cannot be combined with that earth; yet nitric acid dissolves lime readily, which shows us that the refusal of lime and azotic gas to combine is not the consequence of the want of an affinity between these two bodies, but of some other cause.

We may present a body to another with which it is capable of combining in two different states, either insulated or already combined with some other body. Thus we may present lime to nitric acid, either in the

state of pure lime, or combined with carbonic acid, and consequently in the state of a carbonat.

In the first case the affinity is opposed by the cohesion, and combination does not take place unless that force can be overcome. Hence the reason that combination seldom succeeds well, unless some one of the bodies to be combined is fluid, or is assisted by heat, which has the property of diminishing the force of cohesion. Indeed there are not wanting numerous instances of solid bodies combining together without the assistance of heat; but they are always bodies which have the property of becoming liquid in the act of combination. Thus common salt and snow, muriat of lime and snow, &c. combine rapidly when mixed, and are converted into liquids.

It is to the force of cohesion that the difficulty of dissolving the diamond, the sapphire, and many other natural bodies, is to be ascribed, though composed of ingredients very readily acted on by solvents when their cohesive force is sufficiently diminished. If pure alumina is formed into a paste, and heated sufficiently, it becomes so hard that no acid can act upon it; yet its nature is not in the least changed. By proper trituration it may be again rendered soluble; and when precipitated from this new solution, it has recovered all its original properties. The effect of the fire then was merely to increase the cohesion, by separating all the water, and allowing the particles to approach nearer each other.

Even when the cohesive force of the particles to be combined is not very great, it may be still sufficient to prevent combination from taking place, provided the other body can only approach in a very small mass. Hence the reason that carbonic acid gas, and other elastic fluids, have scarcely any action on the greater number of bodies, though they combine with them readily when the force of cohesion presents no opposition. Thus the oxygen of the atmosphere does not combine with sulphur in its natural state, though it unites with it readily when the sulphur is combined with hydrogen and potash, bodies which diminish its cohesion very considerably, or when it is converted into its integrant particles by the action of heat.

In the second case, or when the body presented to be combined with another is already in combination with some other body, it does not altogether leave the old body and combine with the new, but it is divided between them in proportion to the mass and the affinity of these bodies. Thus, when lime, already in combination with phosphoric acid, is presented to sulphuric acid, it does not altogether leave the phosphoric to combine with the sulphuric acid; but it divides itself between these two acids, part combining with the one and part with the other, according to the respective quantities of each of these acids, and the strength of their affinity for the lime. Chemists had formerly, in a great measure overlooked the modification produced on the action of heterogeneous bodies on each other by the different proportions of each; supposing that in all cases a substance A, which has a stronger affinity for C than B has, is capable of taking C altogether from B, provided it be added in sufficient quantity, how great soever the proportion of B exceeds that of A. Several exceptions, indeed, have been pointed out to this general law. Thus Cavendish ascertained, that lime-water is incapable of depriving air completely of carbonic acid. But Berthollet has demonstrated, that this pretended law never holds; that no substance whatever is capable of depriving another of the whole of a third, with which it is combined, except in particular circumstances, however strong its affinity for that third may be, and in how great a proportion soever it be added. Thus no portion of lime whatever is capable of depriving the carbonat of potash of the whole of its acid. Neither does sulphuric acid decompose phosphat of lime completely, nor ammonia sulphat of alumina, nor potash sulphat of magnesia.

In short, it may be considered as a general law in chemistry, that the smaller the proportion of a body in combination with a given quantity of another body is, with the greater energy is it retained; so that at last the force of its affinity becomes stronger than any direct force that can be applied to separate it. Hence the impossibility of depriving sulphuric acid and several other bodies completely of water.

Berthollet has shown also, that every body, how weak soever its affinity for another may be, is capable of abstracting part of that other from a third, how strong soever the affinity of that third is, provided it be applied in sufficient quantity. Thus potash is capable of abstracting part of the acid from sulphat of barytes, from oxat of lime, phosphat of lime, and carbonat of lime. Soda and lime abstract part of the acid from sulphat of potash, and nitric acid abstracts part of the base from oxalat of lime. Hence it follows that substances are capable of decomposing each other reciprocally, provided they be added respectively in the proper quantity. Indeed this was known formerly to be the case, though it had not been considered as a general law till Berthollet drew the attention of chemists to it. Sulphuric acid decomposes nitrat of potash altogether by the assistance of heat. The nitric acid is driven off, and there remains behind sulphat of potash with an excess of acid. On the other hand, if nitric acid is poured into sulphat of potash in sufficient quantity, it takes a part of the base from the sulphuric acid. In the same manner phosphoric acid decomposes muriat of lead, and muriatic acid on the other hand decomposes phosphat of lead.

COMBINATIONS, in law are persons assembled together unlawfully, with an intent to do unlawful acts; and these offences are punishable before such acts are carried into effect, in order to prevent the consequence of combinations and conspiracies. 9 Rep. 57.

Combinations denote the alterations or variations of any number of quantities, letters, sounds, or the like, in all possible ways.

Father Mersenne gives the combinations of all the notes and sounds in music, as far as 64; the sum of which amounts to a number expressed by 90 places of figures. And the number of possible combinations of the 24 letters of the alphabet, taken first two by two, then three by three, and so on, according to Prestet's calculation amounts to 1391724288887252999425128493402200.

Father Trutchet, in Mem. de l'Acad. shows that two square pieces, each divided diagonally into two colours, may be arranged and combined 64 different ways, so as to form so many different kinds of chequer-work: a thing that may be of use to masons, paviours, &c.

Doctrine of COMBINATIONS.

I. *Having given any number of things, with the number in each combination; to find the number of combinations.*

1. *When only two are combined together.*

One thing admits of no combination.
Two, *a* and *b*, admit of one only, viz. *ab*.
Three, *a*, *b*, *c*, admit of three, viz. *ab*, *ac*, *bc*.
Four admit of six, viz. *ab*, *ac*, *ad*, *bc*, *bd*, *cd*.
Five admit of ten, viz. *ab*, *ac*, *ad*, *ac*, *bc*, *bd*, *be*, *cd*, *ce*, *de*.

Whence it appears that the number of combinations of two-and-two only, proceed according to the triangular numbers 1, 3, 6, 10, 15, 21, &c. which are produced by the continual addition of ordinal series 0, 1, 2, 3, 4, 5, &c. And if n be the number of things, then the general formula for expressing the sum of all their combinations by twos, will be $\frac{n.\overline{n-1}}{1.2}$.

Thus, if $n = 2$; this becomes $\frac{2.1}{2} = 1$.

If $n = 3$; it is $\frac{3.2}{2}$ - - $= 3$.

If $n = 4$; it is $\frac{4.3}{2}$ - - $= 6$, &c.

2. *When three are combined together; then*

Three things admit of one order, *abc*.
Four admit of four; viz. *abc*, *abd*, *acd*, *bcd*.
Five admit of ten; viz. *abc*, *abd*, *abe*, *acd*, *ace*, *ade*, *bcd*, *bce*, *bde*, *cde*. And so on according to the first pyramidal numbers 1, 4, 10, 20, &c. which are formed by the continual addition of the former, or triangular numbers 1, 3, 6, 10, &c. And the general formula for any number n of combinations, taken by threes, is $\frac{n.\overline{n-1}.\overline{n-2}}{1.2.3}$.

So, if $n = 3$; it is $\frac{3.2.1}{1.2.3} = 1$.

If $n = 4$; it is $\frac{4.3.2}{6} = 4$.

If $n = 5$; it is $\frac{5.4.3}{6} = 10$, &c.

Proceeding thus, it is found that a general formula for any number n of things, combined by m at each time, is

$$s = \frac{n.\overline{n-1}.\overline{n-2}.\overline{n-3}\ \&c.}{1.\quad 2.\quad 3.\quad 4.\ \&c.}$$

continued to m factors, or terms, or till the last factor in the denominator be m.

So, in six things, combined by fours, the number of combinations is $\frac{6.5.4.3}{1.2.3.4} = 15$.

3. By adding all these series together, their sum will be the whole number of possible combinations of n things combined by twos, by threes, by fours, &c. And as the said series are evidently the co-efficients of the power n of a binomial, wanting only the first two. 1 and n; therefore the said sum, or whole number of all such combinations, will be $1+1\ ^1-n-1$, or 2^2-n1. Thus if the number of things be 5; then $2^2-5-1=32-6=26$.

II. *To find the number of changes and alterations which any number of quantities can undergo, when combined in all possible varieties of ways, with themselves and each other, both as the things themselves, and the order or position of them.*

One thing admits but of one order or position.

Two things may be varied four ways; thus, *aa*, *ab*, *ba*, *bb*.

Three quantities taken by twos, may be varied nine ways; thus *aa*, *ab*, *ac*, *ba*, *ca*, *bb*, *bc*, *cb*, *cc*.

In like manner four things, taken by twos, may be varied 4^2 or 16 ways; and five things, by twos, 5^2 or 25 ways; and, in general, n things, taken by twos, may be changed or varied n^2 different ways.

For the same reason, when taken by threes, the changes will be n^3; and when taken by fours, they will be n^4; and so generally, when taken by ns, the changes will be n^n.

Hence then, adding all these together, the whole number of changes or combinations in n things, taken both by twos, by threes, by fours, &c. to ns, will be the sum of the geometrical series $n+n^2+n^3+n^4$ - - - - n^n, which sum is $= \frac{n^n-1}{n-1} \times n$.

For example, if the number of things n be 4; this gives $\frac{4^4-1}{4-1} \times 4 = \frac{255}{3} \times 4 = 340$.

And if n be 24, the number of letters in the alphabet, the theorem gives $\frac{24^{24}-1}{24-1} \times 24 = \overline{24^{24}-1} \times \frac{24}{23} =$ 13917242888872529994251284934022oo. In so many different ways, therefore, may the 24 letters of the alphabet be varied or combined among themselves, or so many different words may be made out of them.

COMBRETUM, a genus of the class and order octandria monogynia. The calyx is five-toothed, bell-shaped, superior corolla four-petalled, stam. very long, seed one, four or five angled, angles membranaceous. There are four species, natives of South America and the West Indies.

COMBUSTION. There is perhaps no phenomenon more wonderful in itself, more interesting on account of its utility, or which has more closely occupied the attention of chemists than combustion. When a stone or a brick is heated, it undergoes no change except an augmentation of temperature; and when left to itself, it soon cools again, and becomes as at first. But with combustible bodies the case is very different. When heated to a certain degree in the open air, they suddenly become much hotter of themselves; continue for a considerable time intensely hot, sending out a copious stream of caloric and light to the surrounding bodies. This emission, after a certain period, begins to diminish, and at

last ceases altogether. The combustible has now undergone a most complete change; it is converted into a substance possessing very different properties, and no longer capable of combustion. Thus when charcoal is kept for some time at the temperature of about 800°, it kindles, becomes intensely hot, and continues to emit light and caloric for a long time. When the emission ceases, the charcoal has all disappeared, except an inconsiderable residuum of ashes; being almost entirely converted into carbonic acid gas, which makes its escape, unless the experiment is conducted in proper vessels. If it is collected, it is found to exceed greatly in weight the whole of the charcoal consumed.

The first attempt to explain combustion was crude and unsatisfactory. A certain elementary body, called fire, was supposed to exist, possessed of the property of devouring certain other bodies, and converting them into itself. When we set fire to a grate full of charcoal, we bring, according to this hypothesis, a small portion of the element of fire, which immediately begins to devour the charcoal, and to convert it into fire. Whatever part of the charcoal is not fit for being the food of fire is left behind in the form of ashes.

A much more ingenious and satisfactory hypothesis was proposed in 1665 by Dr. Hooke. According to this extraordinary man, there exists in common air a certain substance, which is like, if not the very same with, that which is fixed in saltpetre. This substance has the property of dissolving all combustibles; but only when their temperature is considerably raised. The solution takes place with such rapidity, that it occasions both heat and light, which in his opinion are mere motions.

About ten years after the publication of Hooke's Micrographia, his theory was adopted by Mayow, without acknowledgment, in a tract which he published at Oxford on saltpetre. We are indebted to him for a number of very ingenious and important experiments, in which he anticipated several modern chemical philosophers; but his reasoning is for the most part absurd, and the additions which he made to the theory of Hooke are exceedingly extravagant. To the solvent of Hooke he gives the name of spiritus nitro-aereus. It consists, he supposes, of very minute particles, which are constantly at variance with the particles of combustibles, and from their quarrels all the changes of things proceed. Fire consists in the rapid motion of these particles, heat in their less rapid motion. The sun is merely nitro-aerial particles moving with great rapidity. They fill space. Their motion becomes more languid according to their distance from the sun; and when they approach near the earth, they become pointed, and constitute cold.

The attention of chemical philosophers was soon drawn away from the theory of Hooke and Mayow to one of a very different kind, first proposed by Beecher, but new-modelled by his disciple Stahl with so much skill, arranged in such an elegant sytematic form, and furnished with such numerous appropriate and convincing illustrations, that it almost instantly caught the fancy, raised Stahl to the highest rank among philosophers, and constituted him the founder of the Stahlian theory of combustion.

According to Stahl, all combustible substances contain in them a certain body, known by the name of phlogiston, to which they owe their combustibility. This substance is precisely the same in all combustibles. These bodies of course owe their diversity to other ingredients which they contain, and with which the flogiston is combined. Combustion, and all its attendant phenomena, depend upon the separation and dissipation of this principle; and when it is once separated, the remainder of the body is incombustible. Phlogiston, according to Stahl, is peculiarly disposed to be affected by a violent whirling motion. The heat and the light, which make their appearance during combustion, are merely two properties of phlogiston when in this state of violent agitation. Ingenious as this theory was, it wanted the support of demonstration. The existence of phlogiston was gratuitously admitted, and every one was at liberty to attach his own idea to the term. The theory accordingly underwent many changes in the hands of Macquer, Priestley, Crawford, and Kirwan, but difficulties multiplied in proportion to the progress of discovery in other departments of the science. The last of these philosophers took much pains to prove that hydrogen performed the office which the Stahlian theory assigned to phlogiston. This he attempted in a treatise published on purpose, entitled, 'An Essay on Phlogiston, and the Constitution of Acids.'

In 1777 the celebrated Swedish chemist, Scheele, published a treatise, entitled, 'Chemical Experiments on Air and Fire,' which perhaps exhibits a more striking display of the extent of his genius than all his other publications. After a vast number of experiments, conducted with astonishing ingenuity, he concluded, that caloric is composed of a certain quantity of oxygen combined with phlogiston; that radiant heat, a substance which he supposed capable of being propagated in straight lines like light, and not capable of combining with air, is composed of oxygen united with a greater quantity of phlogiston, and light of oxygen united with a still greater quantity. He supposes too, that the difference between the rays depends upon the quantity of phlogiston. The red, according to him, contains the least; the violet, the most phlogiston. By phlogiston Mr. Scheele seems to have meant hydrogen. It is needless therefore to examine his theory, as it is now known that the combination of hydrogen and oxygen forms not caloric but water. The whole fabric, therefore, has fallen to the ground; but the importance of the materials will always be admired, and the ruins of the structure must remain eternal monuments of the genius of the builder.

During these different modifications of the Stahlian theory, the illustrious Lavoisier was assiduously occupied in studying the phenomena of combustion. He seems to have attached himself to this subject, and to have seen the defects of the prevailing theory, as early as 1770. The first precise notions, however, of whatever might be the real nature of combustion, were suggested to him by Bayen's paper on the oxydes of mercury, which he heard read before the Academy of Sciences in 1774. These first notions, or rather conjectures, he pursued with unwearied industry, assisted by the numerous discoveries which were pouring in from all quarters; and by a long series of the most laborious and accurate experiments and disquisitions ever exhibited in chemistry, he fully established the existence of this general law: "In every case of combustion, oxygen combines with the burning body." This noble discovery, the fruit of genius,

industry, and penetration, has reflected new light on every branch of chemistry, has connected and explained a vast number of facts formerly insulated and inexplicable, and has new-modelled the whole, and moulded it into the form of a science.

Mr. Lavoisier's explanation of combustion depends upon the two laws discovered by himself and Dr. Black. When a combustible body is raised to a certain temperature, it begins to combine with the oxygen of the atmosphere, and this oxygen during its combination lets go the caloric and light with which it was combined while in the gaseous state. Hence their appearance during every combustion. Hence also the change which the combustible undergoes in consequence of combustion.

Thus Lavoisier explained combustion without having recourse to phlogiston; a principle merely supposed to exist, because combustion could not be explained without it. No chemist had been able to exhibit phlogiston in a separate state, or to give any proof of its existence, excepting only its conveniency in explaining combustion. The proof of its existence consisted entirely in the impossibility of explaining combustion without it. Mr. Lavoisier therefore, by giving a satisfactory explanation of combustion without having recourse to phlogiston, proved that there was no reason for supposing any such principle at all to exist.

But the hypothesis of Mr. Kirwan, who made phlogiston the same with hydrogen, was not overturned by this explanation, because there could be no doubt that such a substance as hydrogen actually exists. But hydrogen, if it is phlogiston, must constitute a component part of every combustible, and it must separate from the combustible in every case of combustion. These were points accordingly, which Mr. Kirwan undertook to prove. If he failed, or if the very contrary of his supposition holds in fact, his hypothesis of course falls to the ground.

Lavoisier and his associates saw at once the important uses which might be made of Mr. Kirwan's essay. By refuting an hypothesis which had been embraced by the most respectable chemists in Europe, their cause would receive an eclat which would make it irresistible. Accordingly, the essay was translated into French, and each of the sections into which it was divided was accompanied by a refutation. Four of the sections were refuted by Lavoisier, three by Bertbollet, three by Fourcroy, two by Morveau, and one by Monge; and, to do the French chemists justice, there never was a refutation more complete. Mr. Kirwan himself, with that candour which distinguishes superior minds, gave up his opinion as untenable, and declared himself a convert to the opinion of Lavoisier.

Thus Mr. Lavoisier, destroyed the existence of phlogiston altogether; and established a theory of combustion almost precisely similar to that which had been proposed long ago by Dr. Hooke. The theory of Hooke is only expressed in general terms, that of Lavoisier is much more particular. The first was an hypothesis, or fortunate conjecture which the infant state of the science did not enable him to verify; whereas Lavoisier was lead to his conclusions by accurate experiments, and a train of ingenious and masterly deductions.

According to the theory of Lavoisier, which is now almost generally received, and considered by chemists as a full explanation of the phenomena, combustion consists in two things: first, a decomposition; second, a combination. The oxygen of the atmosphere being in the state of gas, is combined with caloric and light. During combustion this gas is decomposed: its caloric and light escape, while its base combines with the combustible, and forms the product. This product is incombustible; because its base, being already saturated with oxygen, cannot combine with any more. Such is a short historical detail of the improvements which have been gradually introduced into this interesting part of the science of chemistry. Let us now take more particular view of the subject.

By combustion is meant a total change in the nature of combustible bodies, accompanied by the copious emission of heat and light. Every theory of combustion must account for two things; namely, the change which the body undergoes, and the emission of heat and light which accompanies this change.

Mr. Lavoisier explained completely the first of these phenomena, by demonstrating, that in all cases oxygen combines with the burning body; and that the substance which remains behind, after combustion, is the compound formed of the combustible body and oxygen. But he did not succeed so well in accounting for the heat and the light which are evolved during combustion. Indeed this part of the subject was in a great measure overlooked by him. The combination of oxygen was considered as the important and essential part of the process. Hence his followers considered the terms oxygenizement and combustion as synonymous; but this was improper, because oxygen often unites to bodies without any extrication of heat or light. In this way it unites to azote, muriatic acid, and mercury; but the extrication of heat and light is considered as essential to combustion in common language. The union of oxygen without that extrication is very different from its union when accompanied by it, both in the phenomena and in the product; they ought therefore to be distinguished.

To account for the emission of heat and light, which constitutes a part of combustion, Mr. Lavoisier had recourse to the theory of Dr. Crawford. The heat and the light were combined with the oxygen gas, and separated from it when that gas united to the combustible body. But this explanation, though it answers pretty well in common cases, fails altogether in others. Heat and light were supposed to be combined with the oxygen of the atmosphere, because it is in a gaseous state; and to separate from it, because it loses its gaseous state. But as violent combustions take place when the oxygen employed is solid or liquid, as when it is in the state of a gas. Thus if nitric acid be poured upon linseed-oil, or oil of turpentine, a very rapid combustion takes place, and abundance of caloric and light is emitted. Here the oxygen forms a part of the liquid nitric acid, and is already combined with azote; or, according to the language of the French chemists, the azote has undergone combustion. Now in this case the oxygen is not only in a liquid state, but it has also undergone the change produced by combustion. So that oxygen is capable of giving out caloric and light, not only when liquid, but even after combustion, which is directly contrary to the theory.

Farther: gunpowder, when kindled, burns with great

rapidity in close vessels, or under an exhausted receiver. This substance is composed of nitre, charcoal, and sulphur; the two last of which ingredients are combustible; the first supplies the oxygen, being composed of nitric acid and potash. Here the oxygen is not only already combined with azote, but forms a component part of a solid; yet a great quantity of caloric and light is emitted during the combustion, and almost the whole product of the combustion is in the state of gas. This appears doubly inconsistent with the theory; for the caloric and light must be supposed to be emitted from a solid body during its conversion into gas, which ought to require more caloric and light for its existence in the gaseous state than the solid itself contained.

Mr. Brugnatelli, the celebrated professor of chemistry at Pavia, seems to have been the first who saw this objection in its proper light. He has endeavoured to obviate it in the following manner. According to this very acute philosopher, the substance commonly called oxygen combines with bodies in two states: 1. Retaining the greatest part of the caloric and light with which it is combined when in the state of gas. 2. After having let go all the caloric and light with which it was combined. In the first state, he gives it the name of thermoxygen, in the second of oxygen. Thermoxygen exists as a component part, not only of gaseous bodies, but also of several liquids and solids. It is only in those cases where thermoxygen is a component part of liquids or solids, that caloric and light are emitted. All metals, according to him, combine with thermoxygen; those substances, on the contrary, which by combustion are converted into acids, combine with oxygen. This ingenious theory obviates the objection completely, provided its truth can be established in a satisfactory manner. But as the evidence for it rests almost entirely upon its convenience in explaining several difficult points in the phenomena of combustion, we must consider it rather in the light of an ingenious conjecture than as a theory fully established.

It was long the general opinion of chemists, that light exists in a fixed state in all combustible bodies. The discoveries of Lavoisier induced the greater number of them to give up this opinion, on the supposition that combustion could be explained in a satisfactory manner without it. Indeed the followers of that illustrious philosopher considered it as incumbent upon them to oppose it with all their might, because the fixed light, which had been supposed to constitute a part of combustibles, had been unfortunately denominated phlogiston, a term which they considered as incompatible with truth. The hypothesis, however, occasionally revived; first by Richter and Delametherie, and afterwards in a more formal manner by Gren. But little attention has been paid to it in this country till lately. The very curious phenomena observed by Mr. Chenevix in his experiments on the hyperoxymuriatic acid, induced him to incline to the same opinion.

That the light exists combined with the combustible, will appear exeedingly probable, if we recollect that the quantity which appears during combustion depends altogether upon the combustible. Phosphorus emits a vast quantity, charcoal a smaller, and hydrogen the smallest of all; yet the quantity of oxygen which combines with the combustible during these processes, is greatest in those cases where the light is smallest. Besides, the colour of the light depends in all cases upon the combustible that burns; a circumstance which could scarcely be supposed to take place, unless the light was separated from the combustible. It is well known too, that when vegetables are made to grow in the dark, no combustible substances are formed in them; the presence of light being absolutely necessary for the formation of these substances. These facts, and several others which might be enumerated, give a considerable degree of probability to the opinion that light constitutes a component part of all combustible substances; but they by no means amount to a decisive proof. Nor indeed would it be easy to answer all the objections which might be started against this opinion. At the same time, it will be allowed that none of these objections amount to a positive proof of the falsehood of the hypothesis. It is always a proof of the difficulty of an investigation, and of the little progress which has been made in it, when plausible arguments can be brought forward on both sides of the question.

Were we to suppose that the oxygen employed in combustion contains caloric as a component part, while combustibles contain light, it would not be difficulty to explain what takes place during combustion. The component parts of the oxygen so employed are two; namely. 1. a base; 2. caloric. The component parts of combustibles are likewise two; namely, 1. a base; 2. light. During combustion the base of the oxygen combines with the base of the combustible, and forms the product; while at the same time the caloric of the oxygen combines with the light of the combustible, and the compound flies off in the form of fire. Thus combustion is a double decomposition; the oxygen and combustible divide themselves each into two portions, which combine in pairs: the one compound is the product, and the other the fire which escapes.

COMET, an opake, spherical, and solid body, like a planet, performing revolutions about the sun in elliptical orbits, which have the sun in one of the foci. See Astronomy, p. 177..

COMETARIUM, a curious machine exhibiting an idea of the revolution of a comet about the sun. It is contrived in such a manner, as by elliptical wheels to show the unequal motion of a comet in every part of its orbit. See Instruments Astronomical.

COMETES, a genus of the petandria monogynia class and order. The involucrum is four-leaved, three-flowered; calyx four-leaved, caps. tricoccus. There is one species, a native of Suratte.

COMITUM, in Roman antiquity, a large hall in the forum, where the comitia, or assemblies of the people, were ordinarily held. This hall was a long time open at top, for which reason the assemblies were often interrupted by bad weather. It was first covered in the time of the second Punic war; and according to Rosinus, the counsuls and tribunes were not created in the comitium, but in the Campus Martius.

COMMA, among grammarians, a point or character marked thus (,); serving to denote a short stop, and to divide the members of a period.

COMMANDING *ground*, in the military art, an eminence overlooking any post or strong place. A commanding ground is of three kinds; first, a front ground, being an height opposite to the face of some post, which

plays upon its front. Secondly, a reverse ground, being an eminence that can play upon the back of any post. Thirdly, an enfilade commanding ground, or curtin commanding ground, being an eminence that with its shot can scour all the length of a straight line.

COMMENDAM. When a benifice is void, or to prevent its becoming void, it is commended to the charge of some sufficient clerk, to be supplied till it may be conveniently provided with a pastor. When a parson is made bishop, there is a cession of his benifice by the promotion; but if the king give him power to retain his benefice, he shall continue parson, and is said to hold it in commendam; but it must be always before consecration, for afterwards it comes too late, because the benefice is then absolutely void.

COMMELINA, in botany, a genus of the triandria monogynia class of plants, whose corolla consists of six petals; the exterior three of which are small, oval, and concave, of the dimensions of the perianthium; the three interior and alternate petals are large, roundish, and coloured. The fruit is a naked, roundish capsule, containing three cells, and divided by three valves; the seeds, being two only, are angulated. There are 12 species.

COMMENSURABLE, among geometricians, an appellation given to such quantities as are measured by one and the same common measure: thus if a line A a be equal to 8, and a line B b equal to 4 inches, these two lines will be commensurable, since the same common measure 2, measures them both.

Commensurable *numbers*, whether integers or fractions, are such as can be measured or divided by some other number, without any remainder. Such are 12 and 18, as being measured by 6 or 3.

Commensurable *in power*, is said of right lines, when their squares are measured by one and the same space, or superficies.

Commensurable *surds*, those that being reduced to their least terms, becomes true figurative quantities of their kind, and are therefore as a rational quantity to a rational one.

COMMERCE, the exchange of commodities for other articles, or for some representative of value for which other commodities can be procured. At first, commerce consisted merely in exchanging the surplus of some particular article of produce which an individual possessed beyond what he found necessary for his own use, for the similar surplus of some other article possessed by another individual, which kind of traffic is now generally called barter. By the introduction of metallic and paper money, the operations of commerce were much facilitated, while the increase of population rendered them of greater magnitude: improvements in the art of navigation extended their boundaries, the advancement of science and increase of luxury multiplied the objects of trade, and the various duties and regulations established by different governments rendered the subject more complicated to individuals, but at the same time of increased importance to the state.

The advantages of commerce began to engage the attention of mankind at a very early period. About 1300 years after the Flood, the commerce of the Phœnicians had attained to a considerable extent: they possessed manufactures, entered into commercial partnerships, made long voyages, had resident agents in foreign countries, and had adopted the practice of lending money on bottomry.

The Greeks and Romans, particularly the latter, carried on an extensive trade, considering the imperfect state of navigation. The reign of Augustus was particularly favourable to commerce, as the general peace which then prevailed enabled the merchants to pursue their concerns unmolested. At this period, Malta was famous for its number of workmen and its various manufactures, particularly of fine cloth. The inhabitants were the descendants of the ancient Phœnicians, and, like them, pursued commerce with avidity. Under Tiberius we find the Romans extending their protection to the north; and the town of Havern, the most ancient in Friesland, founded. The cultivation of vines in France, Spain, and Portugal, seems to have increased about this time; and from the inhabitants' neglecting to cultivate corn, and turning much of their arable land into vineyards, we may presume the latter afforded considerable profit. About the year 50, the capital of England was first described as a place famous for merchants and plenty of merchandize.

The establishment of Christianity in the northern parts of Germany, in consequence of the conquests of Charlemagne, produced a connection between those parts and the southern parts of Europe, which naturally led to an interchange of produce, and gradually introduced foreign commerce, in the north. The Germans had, however, previously to this period, cultivated a commercial intercourse with the neighbouring states; which was afterwards much increased by the discovery of valuable mines in Saxony, and the establishment of some manufactures in Flanders.

In the 9th century, the Venetians carried on a very beneficial commerce with the Levant; whence they brought spices, silks, drugs, and fruits from the East in great abundance, and supplied the greater part of Europe with these commodities.

The crusades contributed materially to the revival of commerce during the 12th and 13th centuries, by introducing an acquaintance with the luxuries of the East, which multiplied the objects of foreign trade. About this time, the commercial towns bordering on the coasts of the Baltic, finding their trade much interrupted by pirates, entered into an agreement for mutual support and assistance. This union, which became very celebrated under the title of the Hanseatic league, at first consisted of only twelve towns, but finally of upwards of seventy, including all the principal commercial towns of Europe, and embracing nearly all the foreign trade then carried on.

The invention of the mariner's compass, which enabled trading vessels to make much longer voyages, and led to the discovery of a passage to the East Indies by the Cape of Good Hope, with the settlements made on the coast of Africa, in Arabia, and in India, affected very materially the commerce of the Mediterranean and of the Hanse towns, and threw the principal part of the foreign trade of Europe into the hands of the Portuguese. The Venetians, however, still carried on a great trade with India by way of Egypt, for spices and other eastern commodities: the Indian goods were first landed at Aden in Arabia, carried across that country on camels to the

Red Sea, thence over land to the Nile, down that river to Cairo and Alexandria, and thence transported to Venice, whence the Venetians circulated them through every part of Europe.

The Dutch soon began to rival the Portuguese in trade; and in a little time not only dispossessed them of nearly the whole, but from their industry and skill in navigation, and their attention to the fisheries, acquired an extent of foreign trade considerably greater than had been previously possessed by any European power.

The discovery of America opened a new and extensive field for commercial adventure, while the establishment of manufactures produced new articles of trade. The persecutions of the Spaniards drove great numbers of industrious workmen from the Netherlands into England and other countries, who introduced several manufactures into England, and greatly improved others which were already established. While the different branches of its manufactures were thus improving, its colonial possessions in the East and West Indies were greatly increased, and Great Britain was enabled to rival the Dutch not only in manufactured goods, but also in all the principal articles of colonial produce. During the last century, the trade of Holland has rapidly declined; and since the invasion of that country by the French, has been almost annihilated; while the decided naval superiority long maintained by Great Britain, has extended and secured its commerce, and raised it to a magnitude unparalleled in the history of the world.

The vast extent to which the commerce of this country has expanded, appears astonishing when it is considered how great a proportion of the materials of its manufactures are of foreign produce, and the many duties with which the increase of the national expenditure has loaded most articles of foreign trade. The natural advantages arising from the situation of this country, its formidable navy, and extensive colonial possessions, particularly in the East Indies, have favoured and protected its commercial intercourse; while the accumulated capital of individuals has gradually enabled them to give very considerable credit to their customers, which of late years, while some of the principal European powers have been in a very unsettled state, has been of much importance in increasing the commerce of Great Britain to its present extent.

In the reign of Edward III. the countries with which England had commercial intercourse were chiefly France, Spain, Portugal, Lombardy, Flanders, Brabant, and Germany. The total value of all the commodities exported in one year was reckoned at 294,184*l.*, and of all the imports at only 38,970*l.*, sums that are considerably less than the value of the goods now frequently entered in one day. The exports consisted of wool of the value of 277,606*l.*, leather 96*l.*, and cloths 16,260*l.* The imports were, cloths of the value of 11,083*l.*, wax 815*l.*, wine 3841*l.*, linen cloth, mercery, and grocery, 22,943*l.* The policy of the times was by no means calculated to encourage trade: our merchants were very jealous of foreigners participating in their commercial profits, though it was to such persons they were indebted for the little knowledge of trade they possessed; and the government being at times still more jealous in this respect than individuals, many injudicious restrictive laws were made: among others, an act was passed in 1429, prohibiting persons from selling merchandize to aliens, except for ready money. It was, however, soon found necessary to repeal this prohibition, and permission was then given to sell to aliens, upon giving not more than six months credit.

Charles II. imposed a duty of 5 per cent. on goods exported as well as imported, on domestic manufactures as well as on foreign merchandize, and double taxes on all goods when exported by aliens. In 1672, however, the duties payable by aliens on the exportation of British manufactures were repealed. This salutary principle was still more extended in 1700, by removing the imposts on every kind of woollen goods exported, and on corn, meal, and bread. It was, however, by the law "for the further encouragement of manufactures," passed in 1722, that every one was allowed to export duty-free all kinds of merchandize, the produce of Great Britain, except a few particular articles; wild drugs, and other commodities used for dying, were also permitted to be imported duty-free. This period forms a memorable epoch in commercial policy; and the subsequent increase of trade is the best proof of the wisdom of the regulations then adopted.

The various articles of foreign commerce being subject to great fluctuations in their value, a book of rates was adopted at the custom-house in 1696, for the purpose of valuing uniformly the several articles imported and exported; and consonant to these estimates, the following statement shows the total amount of the imports and exports of Great Britain on an average of four years from the above period, and of each five years subsequent.

Years.	Imports.	Exports.
1700	*L.* 4,956,975	*L* 6,034,724
1705	4,794,071	6,310,945
1710	4,321,717	6,713,246
1715	5,304,343	7,401,946
1720	6,054,800	8,132,669
1725	6,628,280	9,663,528
1730	7,273,342	10,808,213
1735	7,470,454	11,855,227
1740	7,270,743	10,822,696
1745	7,363,079	11,920,982
1750	7,429,739	12,877,129
1755	8,264,834	13,406,530
1760	8,877,145	14,253,377
1765	10,266,644	15,544,627
1770	11,910,778	14,138,469
1775	13,803,842	17,420,309
1780	11,663,211	13,337,562

The American war produced a memorable effect on the foreign trade of this country. Previous to that event, our manufacturers were not much in the habit of exporting on their own accounts. The prohibition in America of importation from this country compelled them to seek new markets, and to improve those already known; and from this date commenced that rapid increase of export to the continent of Europe, which has chiefly enabled us to sustain the burthens of that war, and of those in which we have been since engaged. From the peace of 1783, our manufacturers have almost universally acted as merchants, and shipped their goods on their own account. They have gained possession of the foreign markets, in part

from the superiority of their skill, but far more from the superiority of their capital, which has enabled them to give a credit considerably greater than the exporters of other countries can allow. The rapid increase of our commerce since that time will appear by the following account.

Years.	Imports.	Exports.
1784	*L* 15,272,877	*L* 15,734,062
1785	16,279,399	15,117,649
1786	15,786,072	16,300,730
1787	17,804,014	16,870,114
1788	18,027,188	17,472,408
1789	17,821,102	19,340,548
1790	19,130,886	20,120,121
1791	19,669,782	22,731,995
1792	19,659,358	24,905,200
1793	19,256,717	20,390,180
1794	22,288,894	26,748,967
1795	22,736,889	27,312,338
1796	23,187,319	30,424,184
1797	21,013,956	28,917,010
1798	27,857,889	33,591,777
1799	26,837,431	35,991,329
1800	30,570,605	43,152,019
1801	32,795,557	42,301,701
1802	31,442,318	46,120,962
1803	27,992,464	33,792,386
1804	- -	37,471,388

These accounts, formed from rates of value established above a hundred years ago, must of course give a very inadequate idea of the actual total value of the commerce of this country: the accounts are, however, from the very circumstance of being uniformly made up at the same rates, the more correct in a comparative view, and show a progressive increase, which has arrived to an amount never before known in the commerce of any nation. During the last twenty years it appears that the amount of the imports has more than doubled, and the amount of the exports has increased in a still greater proportion. The declared value of British produce and manufactures exported during the year ending 5th January 1804, was 40,100,642*l.*; the amount of foreign merchandize exported in the latter year was (after correcting the value of coffee, which is rated too high) 10,515,574*l.*; the actual total value of the exports of Great Britain, in the year ending the 5th January 1805, was therefore at least 50,865,216*l.*

Of the total exports of Great Britain, about two-thirds of the corrected official value consists of British produce and manufactures, and one-third of foreign merchandize; of the former little more than one-fourth is exported to the continent of Europe, about the same amount to the United States of America, and the remainder to the East and West Indies, and all other parts. The following statement of the exports of the year 1800 will show the proportions of the commerce of Great Britain with different parts of the world; and the accounts that succeed furnish some particulars of all the principal branches.

In the commercial intercourse between Great Britain and Ireland, a very unjust and oppressive species of policy was long exercised, by which the latter country was debarred from the enjoyment and use of its own resources, to make it entirely subservient to the interests and opulence of the former. It was not suffered to share in the bounties of nature or the industry of its citizens, but was shut out from every species of commerce and restrained from sending the produce of its soil to foreign markets. Under such circumstances it cannot be supposed that its commerce even with the country that monopolized it, could be very great; its amount was as follows:

	Imports.	Exports.
In 1710	*L* 310,846	*L* 285,424
1720	282,812	328,583
1730	294,156	532,698
1740	390,565	628,288
1750	612,808	1,316,600
1760	904,180	1,050,401
1770	1,214,398	2,125,466

At an early period in the last century, some little relaxation of the restrictive system had taken place, and something more had been done in the reign of George II.; but it is only since the year 1780 that the system has been completely done away, and Ireland has enjoyed the natural right of exporting its produce to such places as offer the best market. The want of sufficient capital among its manufacturers, and the defective state of cultivation, will however long retard the advancement of Ireland to that degree of commercial importance of which it is capable. In the mean time a considerable proportion of its imports will continue to consist of the manufactures of Britain.

Value of British manufactures exported from Great Britain to Ireland.

	L.	*s.*	*d.*
In 1791 . . .	1,470,972	7	8
1792 . . .	1,511,844	5	9
1793 . . .	1,055,276	6	2
1794 . . .	1,281,316	15	5
1795 . . .	1,612,270	5	0
1796 . . .	1,781,789	5	6

But though Ireland receives a considerable amount of foreign merchandize as well as manufactured goods from Great Britain, the balance of the commercial transactions between the two countries is certainly considerably in

favour of the former, owing principally to the increased importations by Great Britain of Irish linens, which has amounted of late to upwards of 36,600,000 yards annually. But this unfavourable balance of trade with respect to Great Britain is probably counteracted by other circumstances. The total value of the imports of Ireland from all parts was, in the year ending 5th January 1805, 5,718,945*l.* and the total value of exports, 5,063,073; the latter consisted of Irish produce and manufactures 4,902,915*l.*, and of British and foreign articles 160,158. The total number of vessels which entered inwards was 8019, of which number 7055 were from Great Britain; the total number that cleared outwards was 6624, of which number 5808 were to Great Britain.

The trade with Russia is carried on chiefly from the ports of London, Hull, Liverpool, Newcastle, Bristol, Leith, Dundee, and Grangemouth. The principal articles of import are iron, hemp, flax, tallow, pot-ashes, coarse linens, deals and lath-wood, hog's bristles, &c. The exports consist of broad-cloth and woollen stuffs, refined sugar, cotton, lead, tin, iron and steel ware, earthenware and glass, alum, salt, coals, horses, London porter, and various articles of less importance.

Total amount of imports from Russia.

	England.	Scotland.	Total.
1800	*L.*1,990,295	*L.*391,803	*L.*2,382,098
1801	2,001,663	245,214	2,246,877
1802	1,834,265	347,864	2,182,430

Exports from Great Britain to Russia.

	British Manufactures.	Foreign Merchandize.	Total.
In 1800	*L* 557,374	*L* 467,961	*L* 1,025,335
1801	594,617	325,126	919,843
1802	834,412	541,987	1,376,399

The trade with this country is highly beneficial to Russia, as it is from Great Britain only that it receives a large balance in cash, which enables it to import the wines of France, Spain, and Portugal, brandy, oil, indigo, and many other articles of foreign produce. The total number of vessels that entered inwards from Russia in the year 1804 was 859, of which 830 were British ships: the total number that cleared out for Russia was 661, of which 558 were British.

The exports to Denmark and Norway consist chiefly of West India produce, and other foreign merchandize: of the imports, timber and corn are the most considerable.

Years.	Imports.	Exports.
1800	*L* 241,563	*L* 540,698
1801	208,794	416,475
1802	155,672	537,517

The total number of vessels that entered inwards from Denmark and Norway, in the year 1804, was 1418, of which 460 were British ships: the total number that cleared outwards was 1684, of which 713 were British.

The trade between Great Britain and Sweden has remained of nearly the same extent for the last 20 years. It is carried on chiefly in ships of that country; the total number of vessels that entered inwards in 1804 being 252, of which only 106 were British; and the total number that cleared outwards 229, of which only 96 were British.

Years.	Imports.	Exports.
1801	*L* 295,645	*L* 111,254
1802	327,350	108,296
1803	288,651	98,045

The imports consist principally of iron of a superior quality to that of any other country, pitch, tar, deal boards, and sail-cloth. The exports are chiefly colonial produce.

The trade with Prussia is likewise carried on principally in foreign vessels; the total number of vessels from that country which entered inwards in the ports of Great Britain in the year 1804, being 1911, of which only 720 were British, and the total number that cleared outwards 1622, of which only 390 were British vessels.

Years.	Imports.	Exports.
1801	*L* 1,387,149	*L* 660,739
1802	1,057,602	1,071,896
1803	831,225	1,916,502

The export to Prussia is chiefly colonial produce, as the manufactured goods of other countries have of late years been much discouraged by the government, with the view of promoting its own manufactures.

The trade with Germany had not been subject to any great fluctuation with respect to its extent, from the commencement of the last century till the year 1794, when it suddenly became the channel through which the principal part of the continent has since procured the goods which before they had received direct from England. The following account of exports to Germany shows the rapid increase of trade with that country in the course of a few years.

Years.	British Manufactures.	Foreign Merchandize.
1791	*L* 778,213	*L* 1,111,532
1792	811,140	1,327,970
1793	718,474	1,764,221
1794	1,634,530	4,308,695
1795	1,760,133	6,311,876
1796	1,591,810	6,582,179

The produce and manufactures of Great Britain exported to Germany, with the exception of consignments to particular mercantile houses, are sold at the great fairs of Frankfort, Leipzig, Brunswick, and Nuremberg. The Easter fair at Leipzig is greatly celebrated for the immense quantities of British manufactures sold there. Towards the end of March, numberless bales of muslins, calicoes, printed cottons, and other goods, are sent from Glasgow, Paisley, Manchester, &c. to Hamburgh, besides vast quantities of English hardware from Birmingham, as buttons, buckles, saddlery, and a thousand various articles, useful or ornamental: for though the Germans possess many of the materials of at least equal quality, and the wages of workmen are much lower, it will be long before they can rival England in such articles, from the superiority it derives from the use of powerful machinery, and a great division of labour.

Total amount of imports from Germany.

	England.	Scotland.	Great Britain.
In 1800	*L* 2,182,927	*L* 169,270	*L* 2,352,197
1801	1,900,936	143,238	2,044,175
1802	1,070,941	121,089	1,192,030

Total exports to Germany.

	British Manufactures.	For. Merchandize.	Total.
In 1800	*L* 4,364,120	*L* 8,300,471	*L* 12,664,591
1801	4,928,617	6,186,687	11,115,304
1802	3,992,601	6,322,765	10,315,366

The total number of vessels that entered inwards from Germany, in the year 1804, was 189, and the number that cleared outwards 300.

The trade with Holland was formerly the principal branch of our European commerce. It was at its height about the year 1745. On the French taking possession of Holland during the late war, the trade with this country was of course in a great measure suspended, particularly during the years 1795 and 1796. Some little relaxation of the restrictions which had been imposed was afterwards found necessary; and on the peace, its commercial connexion with this country immediately revived, till it was checked again by war.

Years.	Imports.	Exports.
1800	*L.* 972,600	*L.* 3,208,613
1801	1,025,958	3,496,744
1802	974,537	4,957,997
1803	630,403	1,565,355

The total number of vessels which entered inwards from Holland, in the year 1804, was 790, and the number which cleared outwards 521.

The export to Flanders was formerly considerable; but of late years the trade with that part of the continent has been carried on through other ports. The value of goods exported to Flanders in 1792 was 1,031,093*l.*, of which 381,287*l.* was British manufactures, and 649,806*l.* foreign merchandize.

Commercial intercourse with France has been so much deranged for some years past, that it would be useless to give any account of the little that remains, which, during the time of war, must be entirely carried on by the vessels of neutral powers. In the year 1792, the exports to France amounted to 1,228,165*l.*, of which 743,280*l.* was British manufactures, and 484,885*l.* foreign merchandize.

The trade with Portugal was formerly a very beneficial branch of our commerce, but has decayed much of late. The balance, which some years ago was greatly in favour of this country, being estimated on an average of thirty years previous to the peace in 1763 at 800,000*l.* per annum, declined to nothing, and has been latterly against this country. The export of grain from Great Britain to Portugal was very much reduced previous to the scarcity in 1800, and the consequent prohibition. The exports consisted almost wholly of British produce and manufactures, the total value of the exports in 1792 being 760,655*l.*, of which 720,984*l.* was British manufactures The imports from Portugal have increased in cotton-wool, wines, and indigo; but the merchants frequently remit cash and bullion to this country in payment of their debts in trade with other countries, though this has not been the case so much lately as formerly. In 1785, the quantity of gold and silver imported into this country from Portugal was 1,101,700*l.*; but in the year 1795 it was reduced to about 186,000*l.*

The following account of the number of ships which entered inwards from Portugal and cleared out for that country, during twelve years, will give some idea of the present extent of this trade, and of the effect of war with respect to the employment of neutral vessels.

	Inwards.		Outwards.	
Years.	British.	Foreign.	British.	Foreign.
1789	495	7	215	9
1790	505	6	225	11
1791	553	8	267	17
1792	561	9	285	17
1793	300	29	162	26
1794	345	23	224	28
1795	344	35	211	90
1796	254	26	216	106
1797	294	63	185	73
1798	265	61	229	69
1799	374	57	180	75
1800	270	70	203	126

The totol number of vessels which entered inwards in the year 1804 was 372; the number that cleared outwards 314.

The Mediterranean trade has suffered much interruption since the year 1793: Great Britain, however, still retains a considerable share of it, though certainly less than at former periods. In the year 1792, the exports to Italy and Venice amounted to 963,232*l.*; but they have since fallen much below that amount. The goods usually imported from Venice are currants loaded at Zante or Cephalonia, or some port in the Morea, silks, cream of tartar, glass beads for the East and West Indian and African trades, whisks of rice-weeds, sponge, and some Levant drugs, cotton, oil, and vallonea. The exports to Italy and Venice are pilchards and red-herrings, of which the consumption is considerable, a small quantity of salmon, salted ox-guts, of which about 100 or 150 casks are yearly consumed for making salt puddings, tin, lead and litharge, alum, woollens, and hardware; besides sugars, cocoa, pepper, and other foreign articles. The number of vessels which entered inwards from Venice in the year 1800, was only 4, the number that cleared out 12.

The trade with Turkey has been less disturbed than that of any other part of the Mediterranean, particularly since Malta has been in the hands of the English: this branch of trade is by no means equal in importance to what it has formerly been. The exports consist chiefly of lead in pigs, lead-shot, tin, wrought and cast iron, hardware, cloths and stuffs, glass and earthenware, clocks and watches, West India coffee, sugar, pepper, &c. The imports are cotton-wool, cotton-yarn, silk, mohair, madder, galls, figs, raisins, and a few other articles.

Years.	Imports.	Exports.
1801	141,137*l.*	172,198*l.*
1802	182,424*l.*	180,000*l.*
1803	175,427*l.*	155,369*l.*

The number of vessels that entered inwards from Turkey, in the year 1803, was 27; in 1804, 16.

The West India trade is in some respects the most important branch of our commerce. The capital engaged in it has been stated at no less than 70,000,000*l.* The value of the goods exported from Great Britain on an average of four years, ending 5th January 1796, was estimated, according to their real value, at 3,900,000*l.*; but besides the goods sent directly hence to the West In-

dies, merchandize to a considerable amount is exported to the coast of Africa, for the purchase of slaves. Adding, therefore, the value of the slaves annually imported and retained in the islands, the whole export to the West Indies may be estimated at least at 4,672,000*l.* The value of the imports is considerably greater; and the annual balance is to be considered in part as a remittance of the income or property of persons who possess estates in the West Indies, and who are wholly or occasionally resident here; and of persons who have lent money on mortgage or otherwise in the West Indies, and receive the interest through the medium of these remittances: a further part defrays the freight and other charges in this country of West India produce.

Total imports from the West Indies.

	British West Indies.	Conquered Islands.	Total.
1801	6,759,617*l.*	4,105,839*l.*	10,865,456*l.*
1802	7,293,316	2,699,504	9,992,820
1803	5,786,432	362,014	6,148,436

The number of British vessels that entered inwards, in the year 1804, was 714, containing 202,974 tons, and navigated by 11,819 seamen. The number of vessels that cleared outwards was 785.

The trade with the United States of America has rapidly advanced to considerable importance; and we now supply them with commodities to a far greater amount than in the most favourable years previous to their separation from this country. The imports consist chiefly of unmanufactured American produce, such as corn, tobacco, rice, &c. of which about four-fifths of the tobacco is re-exported. In the year ending 5th January 1793, the number of British ships in the trade between this country and the Anglo-American ports was only 193, while the American vessels in the same trade were no less than 313. In the year ending 5th January 1805, the number of British vessels which entered inwards was only 72, while the American vessels were 363; and unless the British shipmasters can advantageously maintain a competition with those of America, we shall soon lose this important branch of our carrying navigation. The exports of Britain to America consist of British manufactures only; for which America will in all probability long continue an improving market.

The export to Canada, and the remaining possessions of Britain in North America, amounted, in the year 1792, to 1,120,091*l.*, of which 908,105*l.* was in British manufactures, and 211,886*l.* in foreign merchandize: it has since been rather under this amount. The imports consist of skins and furs of all kinds. The total number of vessels which entered inwards, in the year 1804, was 270, the number which cleared outwards 384.

The East India trade is a concern of vast magnitude, if considered merely in a commercial point of view. The annual sales of the imports of the company for 16 years preceding 1757, amounted to about 2,055,000*l.* on the average; during the succeeding 10 years, their sales of imports increased to 2,150,000*l.* per annum; in the following 10 years they rose to 3,330,000*l.* per annum. During the American war, the sales of imports fell off about 200,000*l.* per annum; but from that period to 1792, they increased again, and amounted on an average to 4,761,242*l.* The accounts of the following years show a still greater increase.

Amount of the East India company's sales in the years ending 1st March, 1801, 1802, 1803, and 1804.

	India.	China.	Total.
1801	*L.*3,978,800	*L.*3,616,381	*L.*7,595,181
1802	3,086,943	3,539,404	6,626,347
1803	2,289,274	3,753,252	6,042,526
1804	2,236,396	3,629,677	5,866,073

The exports to India are chiefly woollens, metals, and naval and military stores; for the purchase of teas in China a considerable amount of bullion is annually exported. The investments in India are formed from the proceeds of the exports of the company, from the proceeds of part of the territorial revenues invested in merchandize, and from the fortunes of private individuals and the profits of their trade remitted to this country, which are paid into the company's exchequer, and remitted by the company in merchandize from India.

The trade to Africa is chiefly for the purchase of slaves to supply the West India islands. The total number of vessels which entered inwards from Africa in the year 1804 was 38, the number which cleared outwards was 176.

The vast extent of the foreign commerce of Great Britain has been shown from the custom-house accounts of the imports and exports: it will be further illustrated by the following statement of the whole number of merchant-vessels, the amount of their tonnage, and the number of men and boys usually employed in navigating them, which belonged to the several ports of the British empire on the 30th September, 1804.

Great Britain.

Ships.	Tons.	Men.
17,794	2,017,240	134,032

Ireland.

Ships.	Tons.	Men.
1,061	58,060	5,176

The Colonies.

Ships.	Tons.	Men.
2,870	196,628	15,091

Total.

Ships.	Tons.	Men.
21,725	2,271,928	154,299

This number of vessels, great as it appears, is still increasing; the number of new vessels each year considerably exceeding the losses to which such an extensive navigation must unavoidably be subject. The number of vessels built and registered in the different ports of the British empire, in the year ending the 5th January, 1804, was 1402; and the amount of their tonnage 135,349 tons.

COMMERSONIA, a genus of the pentagynia order, in the pentandria class of plants. The calyx is a monophyllous, five-parted, coroliferous perianthium, with sharp ovated segments; the carolla has five linear petals; the stamina are five very short filaments at the bases of the petals; pericarpium a globular, hard, quinquelocular nut, with two ovated seeds in each division. There is one species, a tree of Otaheite.

COMMISSARY, a title of ecclesiastical jurisdiction, appertaining to one who exercises spiritual jurisdiction in places so remote from the chief city, that the chancellor cannot call the subjects to the bishop's principal consistory, without exposing them to great inconvenience.

Commissary *general of the musters*, an officer appoint-

ed to muster the army, as often as the general thinks proper, in order to know the strength of each regiment and company, to receive and inspect the muster-rolls, and to keep an exact state of the strength of the army.

COMMISSARY *general of stores*, an officer in the artillery, who has the charge of all the stores, for which he is accountable to the office of ordnance.

COMMISSARY *general of provisions*, an officer who has the inspection of the bread and provisions of the army.

COMMISSION, is taken for the warrant or letters patent, that all men exercising jurisdiction, either ordinary or extraordinary, have for their power to hear or determine any cause or action; thus the judges and most of the great officers judical and ministerial of this realm, are made by commission.

COMMISSION *of bankruptcy*. See BANKRUPT.

COMMISSION *of delegates*, a commission under the great seal, directed to certain persons usually two or three temporal lords, as many bishops, and two judges of the law, authorising them to sit upon an appeal to the king, in the court of chancery, from a sentence given by the archbishop in any ecclesiastical cause.

COMMISSION *of lunacy* issues out of the court of chancery, to inquire whether a person represented to be a lunatic is so or not.

COMMISSION *of peace*. See JUSTICE *of the peace*.

COMMISSION *of rebellion*, generally termed a *writ of rebellion*, issues where a person, after proclamation made by the sheriff, on a process out of the chancery or exchequer, required, upon pain of his allegiance, to present himself to the court by a day assigned, neglects to appear.

COMMISSION *of sewers* is a commission directed to certain persons, to inspect and see drains and ditches well kept in the marshy and fenny parts of England, for the better conveying of water into the sea, and preserving the grass on the land.

COMMISSION, in commerce. See FACTORAGE.

COMMISSIONER, a person authorised by commission, letters-patent, or other lawful warrant, to examine any matters, or execute any public office, &c. See CUSTOMS, EXCISE, NAVY, TREASURY, &c.

COMMITMENT, is the sending a person to prison by warrant or order, either for a crime or for contumacy. If for a crime the warrant must be until discharged according to law; but for contumacy, until he comply, and perform the thing required. Carth. 153. The commitment should be in writing; otherwise, by the habeas-corpus act, the prisoner may be admitted to bail whatever his offence may have been. 1 Burn. 379.

Who may commit.—Wherever a constable or person may justify the arresting another for a felony, or treason, he may justify the sending him or bringing him to the common gaol. 2 Haw. 116. But it is most advisable, for any private person who arrests another for felony, to cause him to be brought as soon as possible before some justice of the peace, that he may be committed or bailed by him. Dall. c. 118.

The privy-council, or any one or two of them, or a secretary of state, may lawfully commit persons for treason, and for other offences against the state. 2 Haw. 117.

To what place.—All felons shall be committed to the common goal and not elsewhere. 5 Hen. IV. c. 10. But vagrants and other criminals, offenders and persons charged with small offences, may, for such offences, or for want of sureties, be committed either to the common gaol or house of correction, as the justices in their judgment shall think proper. 6 G. c. 19.

Who may be committed.—All persons who are apprehended for offences not bailable, and those who neglect to offer bail for offences which are bailable, must be committed; and wherever a justice of peace is empowered to bind a person over, or to cause him to do a certain thing, he may commit him, if in his presence he shall refuse to be so bound or do such a thing. 2 Haw. 116.

A commitment must be in writing, either in the name of the king, and only tested by the person who makes it; or it may be made by such person in his own name, expressing his office or authority, and must be directed to the gaoler or keeper of the prison. 2 Haw. 119. The commitment should contain the name and surname of the party committed, if known; if not known, it may be sufficient to describe the person by his age, &c. and to add, that he refuses to tell his name. 1 H. H. 557. It ought to contain the causes, as for treason or felony; and also the special nature of the felony, briefly, as for felony for the death of such a one, or for burglary, in breaking the house of such a one. 2 H. H. 122. A commitment must also have an apt conclusion; as if for felony, till he be thence delivered by due course of law. 2 H. H. 123. All commitments grounded on acts of parliament ought to be conformable to the method prescribed by them. 2 Haw. Not. 33. and where a statute appoints imprisonment, but does not limit the time, in such cases the prisoner must remain at the discretion of the court. Dalt. c. 170.

The duty of a gaoler respecting commitments.—If the gaoler shall refuse to receive a felon, or take any thing for receiving him, he shall be punished for the same by the justices of gaol-delivery. 4 Ed. III. c. 9. But no person can justify the detaining a prisoner in custody, out of the common gaol, unless there be some particular reason for so doing; as if the party should be so dangerously ill, that it would apparently hazard his life to send him to gaol, or that there is evident danger of a rescue from rebels or the like. 1 Haw. 118. By the 3 Hen. VII. c. 3. the sheriff or gaoler shall certify the commitment to the next gaol-delivery.

By the habeas-corpus act, the charge of conveying an offender is limited not to exceed 12*d*. a mile.

Commitment discharged.—A person legally committed for a crime, certainly appearing to have been done by some person or other, cannot be lawfully discharged but by the king, till he is acquitted upon his trial, or has an ignoramus found by the grand jury, or none shall prosecute him, on a proclamation for that purpose by the justices of gaol-delivery. 2 Haw. 121.

COMMITTEE *of parliament*, a certain number of members appointed by the house, for the examination of a bill, making report of an inquiry, process of the house, &c.

When a parliament is called, and the speaker and members have taken the oaths, there are committees appointed to sit on certain days, viz. the committee of privileges and elections, of religion, of trade, &c. which are standing committees.

Sometimes the whole house resolves itself into a committee, on which occasion each person has a right to speak and reply as often as he pleases, which is not the case when the house is not in a committee.

COMMODORE, in maritime affairs, an officer of the British navy, commissioned by the lords of the admiralty, or by an Admiral, to command a squadron of men-of-war in chief.

COMMON, is a right or privilege which one or more persons claim to take or use, in some part or portion of that, which another man's lands, waters, woods, &c. naturally produce; without having an absolute property in such lands, woods, waters, &c. 2 Inst. 65.

The general divisions of common are, into common of pasture, which is a right of liberty that one or more have to feed or fodder their beasts or cattle in another man's land. Common of turbary, or a liberty of cutting turves in another man's land or soil. Common of piscary, or a right and liberty of taking fish in another's fish-pond, pool, or river. Common of estovers, which is a right of taking trees or loppings, shrubs and underwood, in another's woods, coppices, &c. and lastly, a liberty which the tenants have in some manors, of digging and taking sand, gravel, stone, &c. in the lord's soil. 1 Bac. Abr. 385.

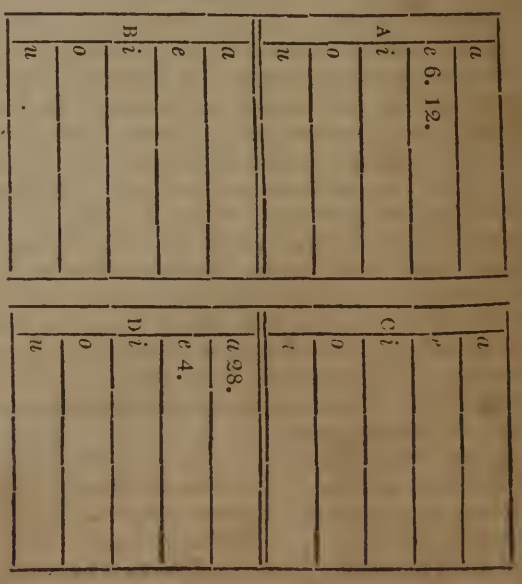
But the word common is usually understood of common of pasture, of which there are four kinds; common appendant, common appurtenant, common in gross, and common by reason of vicinage.

Common appendant, is a right belonging to the owners or occupiers of arable land, to put commonable beasts upon the lord's waste, and upon the lands of other persons within the same manor. Commonable beasts are either beasts of the plough, or such as manure the land. 1 Inst. 122.

Common appurtenant, can only be claimed by prescription, and is a right of commonage for beasts, not only commonable, as horses, oxen, cows, and sheep, but likewise for beasts not commonable, as swine, goats, and geese. Co. Lit. 122.

Common in gross, is a right of commonage which must be claimed by deed or prescription, and has no relation to any land belonging to the commoner; it may be for a certain number of cattle, or without number. He that has common in gross for a certain number of cattle, may put in the cattle of a stranger, and use the common with them. 2 Inst. 427. 2 Rol. Abr. 402.

Common by reason of vicinage, is a liberty that the tenants of one lord, in one town, have to common with the tenants of another town. Those who challenge this kind of common (which is usually called intercommoning) may not put their cattle in the common of the other town, for then they are distrainable; but turning them into their own fields, if they stray into the neighbour common, they must be suffered. Cowel.



A commoner has only a special and limited interest in the soil, but yet he shall have such remedies as are commensurate to his right, and therefore may distrain beasts damage-feasant, bring an action on the case, &c. but not being absolute owner of the soil, he cannot bring a general action of trespass, for a trespass done upon the common. Nor can he do any thing to the soil which tends to the melioration or improvement of it, as cutting down of bushes, ferns, &c. A commoner may abate hedges made on his common: and may drive the beasts of a commoner mixed with the beasts of a stranger to a convenient place to sever them, and may drive the beasts of a stranger out of the common without any custom. Godb. 123. 2 Mod. 65. 3 Lev. 40. It is a general rule, that a commoner cannot distrain or chase out the cattle of the lord, or terre-tenant, damage-feasant; and if the lord surcharge the common, his proper remedy is an action on the case. Godb. 182.

Common intendment, is common meaning or understanding according to the subject matter, and not strained to an extraordinary or foreign sense.

Common Law. The common law of England, is the common rule for administering justice within the kingdom, and asserts the king's royal prerogatives and likewise the rights and liberties of the subject. It is generally that law by which the determination in the king's ordinary courts are guided. It is distinguished from the statute laws or acts of parliament, as having been the law of the land before any acts of parliament which are now extant were made. Hale's Hist. 24. 44. 45.

COMMON-PLACE BOOK is a sort of register, or orderly collection of things worthy to be noted, and retained in the course of a person's reading; and so disposed, as that among a multiplicity of subjects, any one may be easily found.

In Mr. Locke's method, the first page, or first two pages that front each other of the book, serve as a kind of index to the whole. This part is to be divided by paralled lines into twenty-five equal parts; of which every fifth line is to be distinguished by its colour. These lines are to be cut perpendicularly by others drawn from top to bottom, and in the several spaces of which, the several letters, both small and large, of the alphabet, are to be written. The form of the lines and divisions, both horizontal and perpendicular, with the manner of writing the letters, will be readily understood from the following specimen; in which what is to be done in the book for all the letters of the alphabet, is here shown in the first four, A, B, C, and D.

The index thus formed, and the pages of the book numbered, every thing is ready for taking down any passage that is worthy of being registered. We will, for example, suppose the reader desirous of inserting in his common-place book, a passage of poetry. He must consider to what particular head it may most naturally be referred, and under which a person would be led to look for such a thing. The prominent idea, in this instance, is death. D then is the initial letter, and *e* the first vowel: looking into the index for the partition D, and the line *e* (which is the place for all words whose first letter is D, and first vowel *e*, as Death, Deity, Dress, &c.) and finding no numbers already down, which direct to any page of the book where words of this characteristic have been entered, he must turn forward to the first blank page, suppose number 4: here the passage must be written, placing the characteristic word in the margin, thus:

Death. Thou must expire, my soul, ordained to range
Through unexperienced scenes, and mysteries strange,
Dark the event, and dismal the exchange &c. &c.

This being done, the page in which it stands must be, entered in the space De of the index, from which time the 4th and 5th pages are to be devoted to subjects the characteristic letters of which are De.

Again if the reader wishes to insert an argument against anger, revenge, &c. he must determine for himself what is the characteristic of the passage, say anger; he looks for the next vacant page, suppose 6: there he inserts the argument, and in the space Ae he writes 6, the number of the page in which the passage stands, and then the 6th and seventh pages are devoted to subjects the characteristic words of which begin with A and the first vowel is *e*, as anger, angel, &c. When these pages are full, and another passage of the same class is to be entered, look for the next vacant leaf of the common-place book, suppose it to be number 12; at the bottom of p. 7 write *t.* p. 12, which signifies to turn to p. 12, then at the top of p. 12, write 7; enter the passage which is to be registered, and write 12 in the index, which shows that pages 12 and 13 are devoted to subjects whose characteristic words begin with A and the first vowel is *e*.

COMMON PLEAS, pleas or suits regularly divided into two sorts; pleas of the crown, which comprehend all crimes and misdemeanours wherein the king (on behalf of the public) is plaintiff; and common-pleas, which include all civil actions depending between subject and subject. The former of these were the proper object of the court of king's-bench, the latter of the court of common-pleas; and in this court only can real actions, that is, actions which concern the right of freehold or the reality, be originally brought; and in this court also, all other or personal pleas between man and man are determined, but in some of these the court of king's bench has a concurrent authority. But a writ of error, in the nature of an appeal, lies from the court of common-pleas to the court of king's-bench. 3 Black. 37. This court can hear and determine causes removed out of inferior courts by pone, recordare, or other like writs. They can also grant prohibitions, to keep other courts, as well ecclesiastical as temporal, within due bounds.

In this court are four judges, created by letters patent; the seal of the court is committed to the custody of the chief justice.

COMMON PRAYER. It is the particular duty of a clergyman every Sunday, &c. to use the public form of prayer, prescribed by the book of common prayer. And the 13 and 14 Ch. II. enacts that every incumbent residing upon a living and keeping a curate, shall at least once a month, publicly read the common prayer, and if there be occasion, administer the sacraments, and other rites of the church, on pain of 5*l.* to the poor, on confession or conviction thereof before two justices.

COMMUNICATION *of motion*, the act whereby a body at rest is put into motion by a moving body; or it is the acceleration of motion in a body already moving. See MECHANICS.

COMMUNICATION, *lines of*, in military matters, trenches made to continue and preserve a safe correspondence between two forts or posts; or at a siege, between two approaches, that they may relieve one another.

COMOCLADA, a genus of the class and order triandria monogynia. The calyx is three-parted; the corolla the same; drupe oblong with a two-lobed nucleus. There are three species, trees of the West Indies.

COMPANY, in a commercial sense, is a society of merchants, mechanics, or other traders, joined together in one common interest.

When there are only two or three joined in this manner, it is called a partnership; the term company being restrained to societies consisting of a considerable number of members, associated together by a charter obtained from the sovereign. The mechanics of all corporations, or towns incorporated, are thus erected into companies, which have charters or privileges and large immunities. Those of London are very numerous. The mercers were incorporated in the 17th of king Richard II. in the year 1393; the grocers, in the 20th Edward III. ann. 1345; the drapers, in the 17th Henry VI. ann. 1430; the fishmongers, in the 28th of Henry VIII. ann. 1536; the goldsmiths, in the 16th of Richard II. ann. 1392; the skinners, in the 1st of Edward III. ann. 1327; the merchant-taylors, in the 17th Henry VII. ann. 1501; the haberdashers, or hurrers, in 26th Henry VI. ann. 1447, and 17th Henry VII. ann. 1501; the salters, in 20th Henry VIII. ann. 1530; the ironmongers, in 3d Edward IV. ann. 1462; the vintners, in the reign of Edward III. and 15th Henry VI.; and the clothiers, or cloth-workers, in 22d Henry VIII.

Besides these, which are the twelve principal companies of London, there are other very considerable ones; as the dyers, brewers, leather-sellers, pewterers, barbers, surgeons, armourers, white-bakers, wax chandlers, cutlers, girdlers, butchers, saddlers, carpenters, cordwainers, painters, curriers, masons, plumbers, inholders, founders, embroiderers, poulterers, cooks, coopers, bricklayers, and tylers; also bowers, fletchers, blacksmiths, joiners, plaisterers, weavers, fruiterers, scriveners, bottle-makers, and horners; likewise stationers, marblers, wool packers, farriers, paviours, lorimers or loriners, tallow-chadlers, brown-bakers, wood-mongers, upholsterers, turners, glaziers, clerks, watermen, apothecaries, and throwsters.

The word seems now more particularly appropriated to those grand associations set on foot for the commerce

of the remote parts of the world, and vested by charter with peculiar privileges. When companies do not trade upon a joint stock, but are obliged to admit any person properly qualified, upon paying a certain fine and agreeing to submit to the regulations of the company, each member trading upon his own stock, and at his own risk, they are called regulated companies. When they trade upon a joint stock, each member sharing in the common profit or loss in proportion to his share in this stock, they are called joint stock companies. Such companies, whether regulated or joint-stock, sometimes have, and sometimes have not, exclusive privileges.

However injurious companies with joint stock, and incorporated with exclusive privileges, may at this time be reckoned to the nation in general, it is yet certain that they were the general parents of all our foreign commerce, private traders being discouraged from hazarding their fortunes in foreign countries, until the method of traffic had been first settled by joint-stock companies. But since the trade of this kingdom and the number of traders have increased; and the methods of assurance of shipping and merchandize, and the navigation to all parts of the known world, have become familiar to us; experience has shown, that the trade of the nation has advanced in proportion as these monopolies have been discouraged; all restrictions of trade whatever having been found manifestly prejudicial.

1. Regulated companies resemble, in every respect, the corporations of trades, so common in the cities and towns of all the different countries of Europe; and are a sort of enlarged monopolies of the same kind. As no inhabitant of a town can exercise an incorporated trade, without first obtaining his freedom in the corporation; so in most cases no subject of the state can lawfully carry on any branch of foreign trade, for which a regulated company is established, without first becoming a member of that company. The monopoly is more or less strict according as the terms of admission are more or less difficult; and according as the directors of the company have more or less authority, or have it more or less in their power to confine it to themselves and their particular friends. The regulated companies for foreign commerce, which at present subsist in Great Britain, are, the Hamburgh company, the Russia company, the Eastland company, the Turkey company, and the African company.

1. The Hamburgh company is the oldest trading establishment in the kingdom; though not always known by that name, nor restrained to those narrow bounds under which it is now confined. It was first called the company of merchants trading to Calais, Holland, Zealand, Brabant, and Flanders: then it acquired the general title of merchant-adventurers of England; as being composed of all the English merchants who traded to the Low-countries, the Baltic, and the German ocean. Lastly, it was called the company of merchant-adventurers of England trading to Hamburgh. This company was first incorporated by Edward I. in 1296; and their privileges have been confirmed by many of his successors. The revolutions which happened in the Low-countries towards the end of the sixteenth century, and which laid the foundation of the republic of Holland, having hindered the company from continuing their commerce with their ancient freedom, they were obliged to turn it almost wholly to the side of Hamburgh, and the cities on the German ocean; from which the name was changed to that of the Hamburgh, company, though the ancient title of merchant-adventurers is still retained in all their writings.

2. The Russia company was first projected towards the end of the reign of king Edward VI. and executed in the first and second years of Philip and Mary; but had not its perfection till its charter was confirmed by act of parliament, under queen Elizabeth, in 1566. It had its rise from certain adventurers, who were sent in three vessels on the discovery of new countries, and to find out a northeast passage to China: these, falling into the White Sea, and making up to the port Archangel, were exceedingly well received by the Muscovites; and at their return, solicited letters patent to secure themselves the commerce of Russia, for which they had formed an association. This company subsisted with reputation almost a whole century, till the time of the civil wars. It is said, the czar then reigning, hearing of the death of king Charles I., ordered all the English in his states to be expelled; of which the Dutch taking advantage, settled in their room. After the Restoration the remains of the company re-established part of their commerce at Archangel, but never with the same success as before, the Russians being now well accustomed to the Dutch merchants and merchandize. This company subsists still, under the direction of a governor, four consuls, and assistants; and by the 10th and 11th of William III. c. 6. the fine for admission was reduced to 5*l*.

3. The Eastland company was incorporated by queen Elizabeth. Its charter is dated in the year 1579. By the first article the company is erected into a body politic, under the title of the company of merchants of the East; to consist of Englishmen, all real merchants, who have exercised the business thereof, and trafficked through the Sound, before the year 1568, into Norway, Sweden, Poland, Livonia, Prussia, Pomerania, &c. excepting Narva, Muscovy, and its dependencies. Most of the remaining articles grant them the usual prerogatives of such companies; as a seal, governor, courts, laws, &c.

4. The Turkey or Levant company had its rise under queen Elizabeth, in 1581. James I. confirmed its charter in 1605, adding new privileges. During the civil wars, there happened some innovations in the government of the company; many having been admitted members, not qualified by the charters of queen Elizabeth and king James, or that did not conform to the regulations prescribed. Charles II. on his restoration endeavoured to set it upon its ancient basis; to which end, he gave them a charter containing not only a confirmation of their old one, but also several new articles of reformation. By this the company is erected into a body-politic, capable of making laws, &c. under the title of the company of merchants of England trading to the seas of the Levant. The number of members is not limited, but is ordinarily about three hundred. The principal qualification required is, that the candidate be a freeman of London, and a wholesale merchant either by family or serving an apprenticeship of seven years.

5. The company of merchants trading to Africa, established in 1750. Contrary to the former practice with

regard to regulated companies, who were reckoned unfit for such sort of service, this company was subjected to the obligation of maintaining forts and garrisons. It was expressly charged at first with the maintenance of all the British forts and garrisons that lie between Cape Blanc and the Cape of Good Hope; and afterwards that of those only which lie between Cape Rouge and the Cape of Good Hope. The act which establishes this company (the 23d of Geo. II. c. 31) seems to have had two distinct objects in view; first, to restrain effectually the oppressive and monopolizing spirit which is natural to the directors of a regulated company; and, secondly, to force them as much as possible to give an attention, which is not natural to them, towards the maintenance of forts and garrisons.

For the first of these purposes, the fine for admission is limited to forty shillings. The company is prohibited from trading in their corporate capacity, or upon a joint stock; from borrowing money upon a common seal; or from laying any restraints upon the trade, which may be carried on freely from all places, and by all persons, being British subjects, and paying the fine. The government is in a committee of nine persons, who meet in London, but who are chosen annually by the freemen of the company at London, Bristol, and Liverpool; three from each place. No committee-man can be continued in office for more than three years together. Any committee-man might formerly be removed by the board of trade and plantations; now by a committee of council, after being heard in his defence. The committee are forbidden to export negroes from Africa, or to import any African goods into Great Britain. But as they are charged with the maintenance of forts and garrisons, they may for that purpose export from Great Britain to Africa goods and stores of different kinds. Out of the money which they shall receive from the company, they are allowed a sum not exceeding eight hundred pounds for the salaries of their clerks and agents at London, Bristol, and Liverpool; the house-rent of their office in London; and all other expenses of management, commission, and agency, in England. What remains of this sum, after defraying those different expenses, they may divide among themselves, as a compensation for their trouble, in what manner they think proper.

For the second purpose mentioned, the maintenance of the forts and garrisons, an annual sum has been allotted to them by parliament, generally about 13,000*l*. For the proper application of this sum, the committee is obliged to account annually to the cursitor baron of the exchequer; which account is afterwards to be laid before parliament. But it is said great abuses have, notwithstanding, subsisted with regard to this part of the company's engagements.

II. Joint-stock companies, established either by royal charter, or by act of parliament, differ in several respects, not only from regulated companies, but from private copartneries. 1. In a private copartnery no patner, without the consent of the company, can transfer his share to another person, or introduce a new member into the company; each member however may, upon proper warning, withdraw from the copartnery, and demand payment from them of his share of the common stock. In a joint-stock company, on the contrary, no member can demand payment of his share from the company; but each member can, without their consent, transfer his share to another person, and thereby introduce a new member. The value of a share in a joint stock is always the price which it will bring in the market; and this may be either greater or less, in any proportion, than the sum which its owner stands credited for in the stock of the company. 2. In a private copartnery each partner is bound for the debts contracted by the company to the whole extent of his fortune. In a joint-stock company, on the contrary, each partner is bound only to the extent of his share.

The trade of a joint-stock company is always managed by a court of directors. This court indeed is frequently subject, in many respects, to the controul of a general court of proprietors. But the greater part of the proprietors seldom pretend to understand any thing of the business of the company, and give themselves no trouble about it, but receive contentedly such half-yearly or yearly dividend as the directors think proper to make to them. This total exemption from trouble and risk, beyond a limited sum, encourages many people to become adventurers in joint-stock companies, who would upon no account hazard their fortunes in any private copartnery. Such companies, therefore, commonly draw to themselves much greater stocks than any private copartnery can boast of. The principal joint-stock companies at present subsisting in Great Britain are, the South Sea and the East India companies; to which may be added, though of very inferior magnitude, the Hudson's-bay company.

1. The South Sea company. During the long war with France in the reign of queen Anne, the payment of the sailors of the royal navy being neglected, they received tickets instead of money, and were frequently obliged by their necessities to sell these tickets to avaricious men at a discount of 40 and sometimes 50 per cent. By this and other means the debts of the nation unprovided for by parliament, and which amounted to 9,471,321*l*. fell into the hands of these usurers: on which Mr. Harley, at that time chancellor of the exchequer, and afterwards earl of Oxford, proposed a scheme to allow the proprietors of these debts and deficiencies 6 per cent. per annum, and to incorporate them for the purpose of carrying on a trade to the South Sea; and they were accordingly incorporated under the title of "the governor and company of merchants of Great Britain trading to the South Seas, and other parts of America, and for encouraging the fishery," &c.

Some other sums were lent to the government in the reign of queen Anne at 6 per cent. In the third of George I. the interest of the whole was reduced to 5 per cent. and the company advanced two millions more to the government at the same interest. By the statute of the 6th of George I. it was declared, that they might redeem all or any of the redeemable national debts; in consideration of which the company were empowered to augment their capital according to the sums they should discharge; and for enabling them to raise such sums for purchasing annuities, exchanging for ready money new exchequer-bills, carrying on their trade, &c. they might, by such means as they should think proper, raise such sums of money as in a general court of the company should be

judged necessary. The company were also empowered to raise money on contracts, bonds, or obligations, under their common seal, on the credit of their capital stock. But if the sub-governor, deputy-governor, or other members of the company, should purchase lands or revenues of the crown upon account of the corporation, or lend money by loan or anticipation on any branch of the revenue, other than such part only on which a credit of loan was granted by parliament, such sub-governor, or other member of the company, should forfeit treble the value of the money so lent. The fatal South Sea scheme, transacted in the year 1720, and the particulars of which are very generally known, was executed upon the last-mentioned statute.

The South Sea company never had any forts or garrisons to maintain, and therefore were entirely exempted from one great expense, to which other joint-stock companies for foreign trade are subject. But they had an immense capital divided among an immense number of proprietors. It was naturally to be expected, therefore, that folly, negligence, and profusion, should prevail in the whole management of their affairs. Their stock-jobbing speculations were succeeded by mercantile projects which, Dr. Smith observes, were not much better conducted. At length, in the year 1722, this company petitioned parliament to be allowed to divide their immense capital of more than 33,800,000*l.* the whole of which had been lent to government, into two equal parts: the one half, or upwards of 16,900,000*l.* to be put upon the same footing with other government annuities, and not to be subject to the debts contracted, or losses incurred, by the directors of the company, in the prosecution of their mercantile projects; the other half to remain as before, a trading stock, and to be subject to those debts and losses. The petition was too reasonable not to be granted. In 1733 they again petitioned the parliament, that three-fourths of their trading stock might be turned into annuity-stock; and only one-fourth remain as trading stock, or exposed to the hazards arising from the bad management of their directors. Both their annuity and trading stocks had, by this time, been reduced more than 2,000,000*l.* each, by several different payments from government; so that this fourth amounted only to 3,662,784*l.* 8*s.* 6*d.* In 1784 all the demands of the company upon the king of Spain, in consequence of the Assiento contract, were, by the treaty of Aix-la-Chapelle, given up for what was supposed an equivalent; an end was put to their trade in the Spanish West Indies, the remainder of their trading stock was turned into annuity stock, and the company ceased in every respect to be a trading company.

This company is under the direction of a governor, sub-governor, deputy-governor, and 21 directors; but no person is qualified to be a governor, his majesty excepted, unless such governor has, in his own name and right, 5000*l.* in the trading stock; the sub-governor is to have 4000*l.* the deputy governor 3000*l.* and a director 2000*l.* in the same stock. In every general court every member having, in his own name and right, 500*l.* in trading-stock, has one vote; if 2000*l.* two votes; if 3000*l.* three votes; and if 5000*l.* four votes.

2. The East India company. The first, or, as it is called, the old East India company, was established by a charter from queen Elizabeth in 1600; but for some time the partners seem to have traded with separate stocks, though only in the ships belonging to the whole company. In 1612 they joined their stocks into one common capital; and though their charter was not as yet confirmed by act of parliament, it was looked upon in that early period to be sufficiently valid, and nobody ventured to interfere with their trade. At this time their capital amounted to about 740,000*l.* and the shares were as low as 50*l.* Their trade was in general successful, notwithstanding some heavy losses, chiefly sustained through the malice of the Dutch East India company. In process of time, however, it came to be understood that a royal charter could not by itself convey an exclusive privilege to traders; and the company was reduced to distress by the multitude of interlopers, who carried off most of their trade. This contined during the latter part of the reign of Charles II. the whole of that of James II. and part of William III. when, in 1698, a proposal was made to parliament for advancing the sum of 2,000,000*l.* to government, on condition of erecting the subscribers into a new company with exclusive privileges. The old company endeavoured to prevent the appearance of such a formidable rival, by offering government 700,000*l.* nearly the amount of their capital at that time; but such were the exigencies of the state at that time, that the larger sum, though at eight per cent. interest, was preferred to the smaller at one-half the expense.

Thus were two East India companies erected in the same kingdom, which could not but be very prejudicial to each other. Through the negligence of those who prepared the act of parliament also, the new company were not obliged to unite in a joint stock. The consequence of this was, that a few private traders, whose subscriptions scarcely exceeded 7200*l.* insisted on a right of trading separately at their own risk. Thus a kind of third company was established: and by their mutual contentions with one another, all the three were brought to the brink of ruin. Upon a subsequent occasion, in 1700, a proposal was made to parliament for putting the trade under the management of a regulated company, and thus laying it in some measure open. This, however, was opposed by the company; who represented in strong terms the mischiefs likely to arise from such a proceeding. In 1702 the companies were in some measure united by an indenture tripartite, to which the queen was the third party; and in 1708, they were, by act of parliament, perfectly consolidated into one company by their present name of "the united company of merchants trading to the East Indies." Into this act it was thought worthy to insert a clause, allowing the separate traders to continue their traffic till Michaelmas 1711; but at the same time empowering the directors, upon three years notice, to redeem their capital of 7200*l.* and thereby convert the whole capital of the company into a joint stock. By the same act the capital of the company, in consequence of a new loan to government, was augmented from 2,000,000*l.* to 3,200,000*l.* In 1743 another million was advanced to government; but this being raised, not by a call upon the proprietors, but by selling annuities and contracting bond-debts, it did not augment the stock upon which the proprietors could claim a dividend. Thus,

however, their trading stock was augmented; it being equally liable with the other 3,200,000*l.* to the losses sustained and debts contracted by the company, in the prosecution of their mercantile projects. From 1708, or at least from 1711, this company, being freed from all competitors, and fully established in the monopoly of the English commerce to the East Indies, carried on a successful trade; and from their profits made annually a moderate dividend to their proprietors. Unhappily, however, in a short time, an inclination for war and conquest began to take place among its servants; which, though it put them in possession of extensive territories and vast nominal revenues, yet embarrassed their affairs in such a manner, that they have not to this day been able to recover themselves. During the war of 1755, indeed, they acquired the revenues of a rich and extensive territory, amounting as was then said, to near 3,000,000*l.* per annum.

For several years they remained in quiet possession of the revenue arising from this territory, though it certainly never answered the expectations that had been formed concerning it. But in 1767 the British ministry laid claim to the territorial possessions of the company, and the revenue arising from them, as of right belonging to the crown; and the company, rather than yield up their territories in this manner, agreed to pay government a yearly sum of 400,000*l.* They had before this gradually augmented their dividend from about six to ten per cent. that is, on their capital of 3,200,000*l.* they had raised it from 192,000*l.* to 320,000*l.* a year. About this time also they were attempting to raise it still further, viz. from ten to twelve and a half per cent. but from this they were prevented by two successive acts of parliament, the design of which was to enable them to make a more speedy payment of their debts, at this time estimated at more than six or seven millions sterling. In 1769 they renewed their agreement with government for five years more, stipulating, that during the course of that period they should be allowed gradually to augment their dividend to twelve and a half per cent. never increasing it, however, more than one per cent. annually. Thus their annual payments could only be augmented by 608,000*l.* beyond what they had been before their late territorial acquisitions. By accounts from India in the year 1768, this revenue, clear of all deductions and military charges, was stated at 2,048,747*l.* At the same time they were said to possess another revenue, arising partly from lands, but chiefly from the customs established at their different settlements, amounting to about 439,000*l.* The profits of their trade, too, according to the evidence of their chairman before the house of commons, amounted to at least 400,000*l.* per annum; their accountant made it 500,000*l.* and the lowest accountant stated it at least equal to the highest dividend paid to their proprietors. Notwithstanding this apparent wealth, however, the affairs of the company from this time fell into disorder; insomuch that, in 1773, their debts were augmented by an arrear to the treasury in the payment of the 400,000*l.* stipulated; by another to the custom-house for duties unpaid; by a large sum borrowed from the Bank: and by bills drawn upon them from India to the amount of more than 1,200,000*l.* Thus they were not only obliged to reduce their dividend all at once to six per cent. but to apply to government for assistance. Here it may be mentioned in general, that the event proved very unfavourable to the company, as they were now subjected to an interference of government altogether unknown before. Several important alterations were made in their constitution both at home and abroad. The settlements of Madras, Bombay, and Calcutta, which had hitherto been entirely independent of one another, were subjected to a governor-general, assisted by a council of four assessors. The nomination of the first governor and council, who were to reside at Calcutta, was assumed by parliament; the power of the court of Calcutta, which had gradually extended its jurisdiction over the rest, was now reduced and confined to the trial of mercantile causes, the purpose for which it was originally instituted. Instead of it, a new supreme court of judicature was established; consisting of a chief justice and three judges, to be appointed by the crown. Besides these alterations, the stock necessary to entitle any proprietor to vote at the general courts was raised from 500*l.* to 1000*l.* To vote on this qualification, too, it was necessary that he should have possessed it, if acquired by his own purchase and not by inheritance, for at least one year, instead of six months, the term requisite formerly. The court of 24 directors had before been chosen annually; but it was now enacted that each director should for the future be chosen for four years; six of them, however, to go out of office by rotation every year, and not to be capable of being rechosen at the election of the six new directors for the ensuing year. It was expected that in consequence of these alterations the courts, both of the proprietors and directors, would be likely to act with more dignity and steadiness than formerly. But this was far from being the case. The company and its servants showed the utmost indifference about the happiness or misery of the people who had the misfortune to be subjected to their jurisdiction. This indifference, too, was more likely to be increased than diminished by some of the new regulations. The house of commons, for instance, had resolved, that when the 1,600,000*l.* lent to the company by government should be paid, and their bond-debts reduced to 1,500,000*l.* they might then, and not till then, divide eight per cent. upon their capital; and that whatever remained of their revenues and nett profits at home should be divided into four parts; three of them to be paid into the exchequer for the use of the public, and the fourth to be reserved as a fund, either for the further reduction of their bond-debts, or for the discharge of other contingent exigencies which the company might labour under. But it could scarcely be expected that if the company were bad stewards and bad sovereigns when the whole of their nett revenue and profits belonged to themselves, they would be better when three-fourths of these belonged to other people. The regulations of 1773, therefore, did not put an end to the troubles of the company. Among other institutions it had been at this time enacted, that the presidency of Bengal should have a superiority over the other presidencies in the country; the salary of the chief justice was fixed at 8000*l.* per annum, and those of the other judges at 6000*l.* each. In consequence of this act sir Elijah Impey, who was created a baronet on the occasion, set sail, with three other judges, for India in the year

1774. The powers with which they were invested were very extraordinary. They had the title of his majesty's supreme court of judicature in India. Civil law, common law, ecclesiastical, criminal, and admiralty jurisdiction, belonged of right to them. They were empowered to try Europeans on personal actions, and to assess damages, without a jury. Every native, either directly or indirectly in the service of the company, or in their territories, was made subject to their jurisdiction, with a view to prevent the Europeans from eluding justice under the pretence of employing natives in the commission of their crimes: so that in fact they were absolute lords and sovereigns of the whole country.

Such excessive and unlimited powers conferred on any small number of men, could not but be extremely disagreeable to the Europeans, who had been accustomed to enjoy a liberty almost equally unbounded before; nor was it to be supposed that the judges, then suddenly raised from the rank of subjects to the height of despotism, would always use their power in an unexceptionable manner. The design of the establishment was to preserve the commerce and revenues of the company from depredation, by subjecting its servants to the controul of the court; to relieve the subject from oppression by facilitating the means of redress; and to fix a regular course of justice for the security of liberty and property. Instead of considering the circumstances of the country, however, or the manners and customs of the natives, the judges now precipitately introduced the British laws in their full extent, without the least modification to render them agreeable to the Asiatics, who had been accustomed to others of a quite different nature; nor did they even pay the least regard to the religious institutions or habits to which the Indians are so obstinately attached, that they would sooner part with life itself than break through an article of them.

To remedy these and other abuses, in the year 1783, Mr. Fox, then secretary of state, brought in a bill "for vesting the affairs of the East India company in the hands of certain commissioners, and also for the better government of the territorial possessions and dependencies in India." The bill vested the principal power for four years in seven directors, with nine assistant directors, being proprietors, to be nominated in the first instance by parliament; and all future vacancies among the directors to be filled up by his majesty; and all vacancies among the assistant directors to be filled up by the proprietors of India stock, by open poll. The bill passed the commons; but a clamor being raised against it, was rejected by the lords; and the ministry was dismissed. In the following year Mr. Pitt, who succeeded to the administration, brought in a bill, which was afterwards passed into a law, authorising his majesty to appoint certain commissioners from the members of the privy council, to check, superintend, and controul, all concerns, civil and military, of the India company; and in this, which is now called the board of controul, rests the principal direction of the company's affairs; though the court of directors still conduct the commercial business of the company.

In conclusion of this detail we shall only mention the petition last presented to the house of commons by the company. This stated certain pecuniary embarrassments which they apprehended to take place on the 1st of March, 1790, owing to the arrears of the war, to the government claim of 500,000*l.*, to the debt incurred in China, and to the advances necessary to be made for the purposes of the China trade. In compliance with their petition, the chancellor of the exchequer moved, on the following day, that they should be empowered to borrow a sum not exceeding 1,200,000*l.* He at the same time observed, that in all probability the company in 1791 would have upwards of 3,000,000*l.* sterling more than sufficient to discharge their debts. We are sorry to add, this prediction has not been verified.

3. Hudson's-bay company. The vast countries which surround Hudson's-bay abound with animals whose furs and skins are excellent, being far superior in quality to those found in less northerly regions. In 1670 a charter was granted to a company, which does not consist of above nine or ten persons, for the exclusive trade to this bay; and they have acted under it ever since with great benefit to themselves. The company employ four ships, and 130 seamen. They have several forts, viz. Prince of Wales's fort, Churchill river, Nelson, New Severn, and Albany, which stand on the west side of the bay, and are garrisoned by 186 men. The French, in May 1782, took and destroyed these forts, and the settlements, &c. valued at 500,000*l.* They export commodities to the value of 16,000*l.* and bring home returns to the value of 29,340*l.* which yield to the revenue 3734*l.* This includes the fishery in Hudson's-bay. This commerce, small as it is, affords immense profits to the company, and even some advantages to Great Britain in general: for the commodities we exchange with the Indians for their skins and furs, are all manufactured in Britain; and as the Indians are not very nice in their choice, such things are sent of which we have the greatest plenty; and which, in the mercantile phrase, are drugs with us: and although the workmanship happens to be in many respects so deficient, that no civilized people would take it off our hands, it may be admired among the Indians. On the other hand, the skins and furs we bring from Hudson's-bay, enter largely into our manufactures, and afford us materials for trading with many nations of Europe to great advantage. These circumstances tend to prove incontestably the immense benefit that would result to Great Britain, by throwing open the trade to Hudson's-bay, since even in its present restrained state it is so advantageous. This company, it is probable, do not find their trade so advantageous now as it was before we got possession of Canada. The only attempt made to trade with Labrador has been directed towards the fishery, the annual produce of which exceeds 49,000*l.*

Company, in military affairs, a small body of foot, commanded by a captain, who has under him a lieutenant and ensign.

The number of sentinels, or private soldiers, in a company, may be from 50 to 80; and a battalion consists of 13 such companies, one of which is always grenadiers, and posted on the right; next them stand the eldest company, and on the left the second company; the youngest one being always posted in the centre. Companies not incorporated into regiments are called irregulars, or independent companies.

COMPARITIVE ANATOMY has been defined "that branch of anatomy which considers the secondary objects, or the bodies of other animals; serving for the more accurate distinctions of several parts, and supplying the defects of human subjects."

From the general view, however, which we are about to present of this science, it will appear that the above is by no means a correct definition. Comparative does not, in strict propriety, stand in contradistinction to human anatomy; but, on the contrary, while it embraces the whole circle of animated existence, considers man as the standard of its comparisons, and the primary object of its inquiries.

To ascertain the differences among animals in their several organs, is the proper object of comparative anatomy. In treating of this subject, therefore, it is our intention to describe, in the first place, the most important of those varieties; which will lead to a classification or division of animals, founded on the whole of their organization, those being connected in one class which have the nearest resemblance to each other in anatomical characters; we shall then select two individuals of the first classes for the more particular description of the internal organs, especially of the thoracic and abdominal viscera; and conclude by taking a general survey; first of the structure of animal bodies, as it relates to their locomotive powers; and secondly, in reference to the external form and relative quantity of brain or encephalon, as connected with a gradation of the sentient principle and intellectual faculties.

General differences which animals exhibit in their organs of sense and motion.

As the principal characteristics of animal life are sensation and loco-motion, we are naturally led to inquire into the differences of those organs in which the former faculty is found to reside, and likewise into those by which the latter is exerted, for the purpose of establishing a general and obvious classification of the objects of comparative anatomy: accordingly we find the variations of the internal part of the nervous system to present three well-marked divisions; the first of which commencing with the lowest order of animals, comprehends those in which neither vessels nor nerves have hitherto been discovered; such are the zoophytes, or polypi, which perhaps may be regarded as preferring but an equivocal claim to the denomination of animals. The second division consists of those in which there is only the brain above the alimentary canal, while the remaining portion of the common bundle of nerves is situated beneath it, and is contained in the same cavity with the other viscera: these form the class of mollusca, crustacea, insects, and some of the articulated worms. The third division comprehends animals in which the common fasciculus of nerves is placed entirely in the back, and above the alimentary tube, being inclosed within a canal which passes through the vertical column: these are the vertebral animals, in which man is included.

With respect to the external senses, we shall find the difference to consist in the number, and degree of energy, which appertain to each.

All vertebral animals possess the same senses as man.

Sight appears to be wanting in the zoophytes, in several kinds of articulated worms, in many of the insects, and in the acephalous mollusca. The organ of hearing has not been discovered in some of the mollusca and insects. The remaining three senses, but particularly those of taste and touch, appear in no instance to be wanting.

The organs of motion present likewise the three following important and primary distinctions. 1st. The bones either form an internal skeleton, articulated, and covered by muscles; or, 2dly, these last are placed externally, and enveloped by scales or shells: in the last division there is not any hard part that can serve as a lever or fulcrum for motion.

Animals of the first kind have the whole body supported by a bony column formed of distinct pieces, which is called the spine, vertebral column, or back-bone: these, therefore, are the vertebral animals.

The animals destitute of vertebræ, according as they are entirely soft, have their bodies covered with scales, or are enclosed in shells, belong to the classes of soft worms, insects, or crustacea.

Besides, however, the leading distinctions above pointed out from varieties in animal organization and functions, we shall find important differences likewise in those that are called vital and natural functions, and in the organs appropriated to each.

Varieties in the organs of digestion and assimilation.

The organs of digestion afford two leading differences in their general dispositions. In the major part of the zoophytes the intestines from a sac, which has but a single aperture, serving at once for the entrance of the aliment and discharge of the excrement: all other animals have two distinct openings for these purposes (mouth and anus), placed at the two extremities of what is called the alimentary canal.

The chyle, formed by the action of the digestive organs, is transmitted to the several parts of the body in two different ways. It either simply transudes through the sides of the alimentary canal, thus in a manner bathing all the interior of the body, as in the zoophytes, and perhaps in insects; or it is received by a distinct system of vessels, through the medium of which it is conveyed into the mass of blood. Some of those animals that have absorbent vessels, as man, and other of the vertebral class, have the contents of these vessels white, while the blood is red; in others the chyle, lymph, and blood, are of the same colour.

Differences in the organs of circulation, respiration, and voice.

The circulation of the blood itself is accompanied with very considerable differences.

In the first place, there are animals, viz. the insects and zoophytes, which have no circulation; others have a single, and others a double circulation. The reptiles afford an example of a single circulation; while in man, indeed in all the mammalia, as likewise in birds, fishes, and many of the mollusca, it is double.

Where the circulation is single, a great part of the venous blood re-enters the arteries without passing through the lungs: in this manner the blood is distributed in the amphibia. Here there is only one heart; when the circulation is double, there are sometimes one heart at the base of the pulmonary artery, and another at the base of the aorta, or principal artery of the body; and these two hearts are either united, as in man, some

other of the mammalia, and birds; or they are separate, and placed at a distance, as in the genus sepia, or cuttle-fish.

Where there is only one ventricle, it is sometimes placed at the base of the aorta, as in snails and other molluscula, or at the root of the pulmonary artery, as in fishes.

Great varieties are also observable in the organs subservient to respiration. When the element that acts on the blood is atmospheric air, it penetrates the interior of the respiratory organ; while it simply glides over a multiplied surface, when that element is water: in this latter case the lamellæ of which the organ is composed are called gills, or branchiæ: these are common to fishes, and many of the mollusca; in some instances, in place of branchiæ, we meet with fringes, or tufts.

The air penetrates into the interior of the body, either by a single aperture, or by several: the former is observed in all animals which have lungs, properly so called. When there are several apertures, which is the case only in insects, the vessels that receive the air are ramified ad infinitum, and convey it to every part of the body. This last is called respiration by tracheæ.

Lastly, scarcely any of the zoophytes have perceptible organs of respiration.

The organs of voice present but two general differences. In birds the glottis is situated at the interior, in quadrupeds and reptiles it is placed at the superior, extremity of the trachea, and at the root of the tongue. It is only the above three classes of animals that are furnished with a glottis. Sounds are produced in other animals by different means. Sometimes the friction of certain elastic parts is employed for this purpose; sometimes the animal beats the air with other parts, or occasions a rapid motion in certain portions of that air which is retained in its body.

Varieties in the generative organs.

Generation essentially differs both in its mechanism and produce. This function is performed in some of the zoophytes without copulation; and the young animal grows on the body of the parent like the shoots of vegetation. In other animals the sexual organs are either found united in the same individual, as in the mollusca, and some of the zoophytes, or are placed in two separate individuals, as in insects, and all the vertebral class of animals.

Some hermaphrodites, as the bivate shell fish, generate singly; in others of this class a conjunction of two individuals is absolutely necessary for the production of offspring; each individual performing, at the same time, the function of both male and female: this is the case with snails, and other species of mollusca that crawl upon the belly.

The product of generation is either a bud projecting from the parent like the branch of a tree, till completely developed; or a fœtus, which arrives at maturity in the womb of its mother, and from which it issues a living animal; or, finally, it is an embryo, inclosed in a shell, with a substance adhering to, and connected with, it by vessels; which substance it absorbs and converts into nutriment before it is completely hatched. The above varieties form the three modes of generation denominated gemmiparous, viviparous, and oviparous. The first is confined to a few zoophytes and articulated worms; the second takes place in man and other mammalia only; the third is common to all other animals, with the partial exception of those which, although in reality oviparous, are actually generated living animals, on account of the eggs being hatched in the oviduct of the mother. This is the case for instance, with the viper. Some animals have at birth the same form which they afterwards retain. Others vary considerably in their perfect state from the form which they received at birth, and are said therefore to undergo a metamorphosis. Hitherto this change has only been observed in insects, and in reptiles without scales, that is, in frogs and lizards.

Organs of secretion.

The organs of secretion likewise vary materially in different animals: in the zoophytes secretory vessels have not been detected; in insects secretion is effected by tubes of different length; and in the vertebral animals, as likewise in some of the mollusca, this function is performed by glands, or at least vascular expansions.

CLASSIFICATION OF ANIMALS, FOUNDED ON THE WHOLE OF THEIR ORGANIZATION.

The comparative anatomist divides the whole animal kingdom into two great families: the first comprehends those animals which have vertebræ and red blood: the second is composed of those which are destitute of vertebræ, and which, for the most part, have white blood.

The general anatomy of the first class is the following.

Anatomy of vertebral animals with red blood.

The skeleton is invariably covered by fleshy substance, and is articulated. Its principal support is the vertebral column, which always joins the head at its anterior extremity, and is frequently prolonged at its posterior extremity to form the tail. The ribs, which are constantly met with in animals of this class, are attached to both sides of the spine. There are never more than four limbs; two, or all of which, are sometimes wanting. The brain is always contained in the cranium; the senses are invariably five in number; the eyes are two; the ear has at least three semicircular canals; the sense of smell has always its seat in the cavities at the anterior part of the head.

The circulation is maintained by a heart consisting of at least one ventricle: if there are two, these are never separate. The absorbent is distinct from the venous system.

The two jaws are situated horizontally: the mouth always opens by their separation from above downwards. The intestinal canal is continued from the mouth to the anus, which is uniformly found at the posterior part of the pelvis. The intestines are surrounded by a peritoneum. A liver, pancreas, and spleen, are always met with.

The kidneys are placed on each side the spine and without the peritoneum. The testicles are two in number. Above the kidneys two bodies are found, the use of which has not hitherto been discovered.

This first class is again subdivided into two branches, consisting 1st of animals with warm blood, and 2dly of animals with cold blood.

Vertebral animals with warm blood.

The first of these have invariably two ventricles and a double circulation. Animals of this class cannot exist

without respiration. Their brain occupies the whole cavity of the cranium. Their eyes close by palpebræ. The tympanum of the ear is sunk in the scull. The labyrinth of this organ is enveloped by the bone; and there is always observed in it, besides the semicircular canal, an organ resembling the shell of a snail (cochlea). Their nostrils have a communication with the back of the mouth. Their trunk is invariably surrounded with ribs; the greater number of this class of animals have four limbs.

With cold blood.

The second subdivision of this first class, the vertebral animals with cold blood, are frequently without ribs; some have no articulated limbs. Their brain never fills up the whole cavity of the cranium. The eyes are seldom furnished with moveable palpebræ. When there is a tympanum to the organ of hearing, it is always level with the head. The cochlea is wanting. The various parts of the ear are not attached closely to the cranium; sometimes they are at liberty in the same cavity with the brain.

Each of these two branches of vertebral animals, is again subdivided into two classes; the two divisions of the first branch are the mammalia and birds.

First class of vertebral animals with warm blood—THE MAMMALIA.

The mammalia are viviparous: they nourish their young with milk which is furnished by their mammæ; they have always an uterus with two cornua; the males have a penis, which in copulation is introduced into the genital organ of the female.

The head of the mammalia is jointed to the first vertebra by two eminences: the cervical vertebræ are never less than six, nor more than nine; the brain is extremely complicated: it has parts which are not met with in other classes of animals, such as the corpus callosum, fornix, pons Varolii, &c. See ANATOMY.

The eyes of the mammalia have only two palpebræ; their ears have four articulated bones, and a spiral cochlea; their tongue is soft and fleshy: the skin is in a great number of instances covered with hair, and there is some hair on all of them.

The lungs are enclosed within the thorax: there is always a diaphragm: there is only one larynx, which is situated at the base of the tongue, and covered by the glottis during deglutition.

The inferior maxilla only is moveable; both jaws are furnished with lips.

The biliary and pancreatic ducts are inserted at the same point: the lacteal vessels contain a milky chyle, and pass through the mesenteric glands. The epiploon covers the anterior portion of the intestines.

The spleen is invariably situated on the left side; between the stomach, ribs, and diaphragm.

Second class—AVES.

Birds are oviparous; they have but one ovarium and one oviduct, a structure peculiar to this class. The head is connected with the vertebræ by one eminence only: the vertebræ of the neck are very numerous. The sternum is much expanded: the anterior members are only used in flying, the posterior in walking.

The eyes of birds have three palpebræ; they have no external ear: the tympanum has only one bone: the cochlea is in the form of a cone slightly twisted: the tongue has a bone internally; the body is covered with feathers; the lungs are attached to the ribs; in the act of inspiration air is communicated to all the body, as birds have no diaphragm. The windpipe has a larnyx at each extremity; the upper extremity is without an epiglottis. Their mouth is formed by a bill or beak of a horny consistence, the two mandibles of which are moveable.

Several ducts pass out from the pancreas and liver, and penetrate the intestinal canal at different parts. The chyle is transparent, and there are neither mesenteric glands nor omentum. The spleen is in the centre of the mesentery.

The urinary ducts (ureters) terminate in a cavity called the cloaca, which is the receptacle both of the excrements and eggs. Birds have no urinary bladder.

General anatomy of animals with cold blood belonging to the vertebral class; these are reptiles and fishes: third class of animals—REPTILES.

There is less uniformity in the organization of reptiles than in that of any other class; some walk, some fly, others swim, and many can merely crawl. Their organs of sensation, particularly the ear, exhibit nearly as many varieties as those of motion. Reptiles are however universally without cochlea; their skin is either naked, or enveloped with a scaly covering: their brain is invariably small; the lungs are contained in the same cavity with the other viscera, but they do not admit the air to pass beyond them. The pulmonary cells are very capacious; there is only one larynx which has an epiglottis: both the jaws are moveable; they are without omentum or mesenteric glands; the spleen, as in birds, is in the centre of the mesentery. The female has two ovaries and two oviducts; reptiles have an urinary bladder.

Fourth class—PISCES.

Fishes respire by organs in the shape of gills situated on either side of the neck, between which they transmit the water; they have therefore no trachea, larynx, nor voice; their bodies are formed for swimming, but they have sometimes no fins. Besides the four which represent the extremities, they have vertical fins on the back, under the tail, and at its extremity.

Their nostrils do not assist them in respiration: their ear is concealed within the cranium: their skin is either without any covering, or is scaly; their tongue is bony; each jaw is moveable; the intestinula cœca often occupy the place of the pancreas; they have an urinary bladder: their ovaries are double.

General anatomy of animals without vertebræ.

The organization of the second family of animals, the invertebral, presents a less regular series to assist the comparative anatomist in his classification. If animals of this class have an articulated and hard skeleton, it is for the most part external. Their nervous system, instead of being enclosed in a bony case, floats in the same cavity with the other viscera. The brain furnishes two branches which envelope the œsophagus; the continuation of these branches forms the remainder of the common mass of nerves.

Animals without vertebræ never respire by cellular lungs; and in no instance have they voice: their jaws have various directions, and often their mouths are merely suckers; they have neither kidneys nor urine; if they

have articulated members they are always at least six in number. The invertebral animals may be divided into five classes; the mollusca, crustacea, insects, worms, and polypi or zoophytes.

First order of invertebral animals, forming the fifth general class—MOLLUSCA.

The body of the mollusca is soft, fleshy, and destitute of articulated members: sometimes they have hard parts situated internally. They respire by branchiæ. Their brain is a distinct mass, from which proceed the nerves and a medulla oblongata. They have ganglions. Their external senses vary with respect to number. In some the eyes and ears are perceptible, while in others we are not capable of detecting any other senses than those of taste and touch. Many of the mollusca can masticate, while others can merely swallow. This class of animals has a voluminous liver, which secretes a large quantity of bile. Their generative organs are exceedingly various.

Sixth class—CRUSTACEA.

In the crustacea the body is covered with scales: these animals have often a considerable number of articulated members; their nervous system is composed of a long knotted cord, from the ganglions of which all the nerves are distributed. The crustacea have hard moveable eyes; their ears are very imperfect in their organization: the sense of touch is furnished by antenæ and feelers, as in insects: they have a heart with arterial and venous vessels, and they respire by branchiæ: their jaws are transverse, strong, and numerous; teeth are found in the stomach; a number of intestinula cœca afford a brown fluid, which appears to supply the office of bile. The male of the crustacea has two penes, the female two ovaria.

Seventh class—INSECTA.

Insects have antennæ and articulated members, like the crustacea. Some of these animals have wings, in which case they have existed in different forms, and in certain stages of their existence have been entirely motionless. Insects have a nervous system, like that of the crustacea; they have, however, neither heart nor vessels, and respire only by tracheæ. Not only the liver, but all the secretory glands, are in insects replaced by long vessels, which float in the abdomen. As the animal passes through its different states of existence, the form of the intestinal canal varies considerably in the same individual.

Eighth class—VERMES.

These animals, which greatly resemble the insect tribe, might be joined with insects, but they do not undergo a metamorphosis. Some of them have a distinct vascularity, and they may be regarded as forming an intermediate class between the mollusca, crustacea, and insects; such are the terrestrial worms, and leeches.

Ninth class—ZOOPHYTA.

The parts of the body in this class of equivocal animals are formed like the radii of a circle, in the centre of which the mouth is placed. The anatomist has not hitherto been able to trace in the zoophytes, heart, blood-vessels, brain, or nerves.

The following table will present at one view, without the necessity of detail, the various subdivisions of the classes of animals above described. To render this description more intelligible, the Linnæan classification and generic names of animals have been connected with the anatomical divisions and nomenclature.

MAMMALIA.

A. With nails.

a. Having each kind of teeth.

I. Thumbs only separate on the superior extremities.—Genus homo; of the primates of Linnæus.—*Bimana.*

II. Thumbs separate on all four feet.—Genera simia, lemur; primates Linnæi.—*Quadrumana.*

III. On the fore feet, no thumbs separate.

1. Hands elongated; membranes from the neck to the anus.—Gen. vespertilio, galeopithecus; primates Lin.—*Chiroptera.*
2. The whole of the soles of the feet resting on the ground.—G. erinaceus, sorex, talpa, ursus; feræ Lin.—*Plantigrada.*
3. Feet resting only on the toes.—G. mustela, viverra, felis, canis; ferae Lin.—*Carnivora.*
4. Thumbs separate on the hind feet.—Genus didelphis; feræ Lin.—*Pedimana.*

b. Without some kinds of teeth.

IV. Without canine teeth.—G. kangarus, hystrix, lepus, cavia, castor, sciurus, chcioromys, mus; glires Lin.—*Rodentia.*

V. With no incisive or canine teeth.—Gen. myrmecophaga, orycteropus, dasypus; bruta Lin.—*Edentula.*

VI. Without incisive teeth.—G. bradypus; bruta Lin.—*Tardigrada.*

B. With hoofs.

VII. More than two toes and two hoofs.—G. elephas; bruta Lin. Sus, hippopotamus, hyrax, and rhinoceros; belluæ Lin.—*Pachodermia.*

VIII. With two toes and hoofs.—Pecora Lin.—*Ruminantia.*

IX. One toe and one hoof.—G. equus; belluæ Lin.—*Solipeda.*

C. With finny feet.

X. Four feet.—G. phoca; feræ Linnæi: and trichecus, bruta Lin.—*Amphibia.*

AVES.

I. Feet short, toes with long claws, beak hooked.—Accipitres Lin. except lanius.—*Accipitres.*

II. Four toes, three anterior and one behind; external toes entirely or partially joined.—G. laneus; passeres Lin. except columba, and some of the picæ.—*Passeres.*

III. Two anterior toes and two behind.—Part of the G. picæ Lin.—*Scansores.*

IV. Anterior toes united at their base by a short membrane.—Gallinæ, and some of the grallæ, Lin.—*Gallinæ.*

V. Legs long and naked.—Most of the grallæ Lin.—*Grallæ.*

VI. Toe united by extensive membranes.—Anseres Lin.—*Anseres.*

REPTILES.

A. Heart with two auricles.

I. Upper part of the body enveloped by shell, jaws covered with horn.—G. testudo; reptiles pedati Lin.—*Chelonii.*

II. Body covered with scales, teeth.—Reptiles pedati Lin.—*Saurii.*

B. Heart with only one ventricle.

III. Body covered with scales, no feet, no branchiæ at any period.—Serpentes apodes Lin.—*Ophidii.*
IV. Skin naked, feet, branchiæ in the first period.—Reptiles pedati Lin.—*Batrachii.*

PISCES.

A. Skeleton cartilaginous.
I. Branchiæ fixed. Part of the amphibia nantia Lin.—*Chondropterygii.*
II. Branchiæ loose. Part of the amph. nan. Lin.—*Branchiostegi.*

B. Skeleton bony.
III. No ventral fins.—Apodes Lin.—*Apodes.*
IV. With ventral fins anterior to the pectoral.—Jugulares Lin.—*Jugulares.*
V. Ventral fins below the pectoral.—Thoracici.—*Thoracici.*
VI. Ventral fins behind the pectoral.—Abdominales Lin.—*Abdominales.*

MOLLUSCA.

I. Head with tentacula supplying the place of feet.—Sæpia belonging to the mollusca, and argonauta and nautilus to the cochleæ, Lin.—*Cephalopoda.*
II. Head free, and which crawl on the belly.—Cochleæ Lin.—*Gasteropoda.*
III. Without a distinct head.—Principally conchæ Lin.—*Acephala.*

CRUSTACEA.

I. *Monuculus.*
II. *Cancer.*

INSECTA.

A. With jaws.
I. No wings.—*Gnathaptera.*
II. Four reticulated wings.—*Neuroptera.*
III. Four veined wings.—*Hymenoptera.*
IV. Four wings, superior hard, inferior folded transversely.—*Coleoptera.*
V. Four wings, superior hard, inferior folded longitudinally.—*Orthoptera.*

B. Without jaws.
VI. Four wings much crossed, rostrum articulated.—*Hemiptera.*
VII. Four wings covered with scales, trunk spirally convoluted.—*Lepidoptera.*
VIII. Two wings only.—*Diptera.*
IX. No wings.—*Aptera.*

VERMES.

I. With external organs of respiration, and hairs on the sides of their bodies.—Some of the mollusca, and some of the testacea, Lin.
II. Without external organs of respiration.
1. Hairs on the sides of the body.—Nais, lumbricus, thallaserna.
2. No hairs on the side of the body.—Hirudo, fasciola, planaria, gordius.

Animals bearing a resemblance to the vermes, the organization of which is not sufficiently known to determine whether they belong to that order, or ought to form one contiguous to the zoophyta.

1st family.—Tenia, hydatigenia, ligula, linguatula.
2d family.—Ascaris, and some other intestinal worms.

ZOOPHYTA.

A. Not attached.
I. With a calcareous or coriaceous envelope, and intestines floating in the interior cavity.—*Echinodermia.*
II. With a fleshy or gelatinous envelope, intestines hollow, and adhering in the mass of the body.—*Urticaria.*
III. Very small, swimming in fluids.—*Infusoria.*
IV. Gelatinous bodies, increasing by buds.—*Polypi.*

B. Attached to a solid trunk.
V. In which the medullary substance crosses a corneous axis, and terminates in polypi on its branches.—*Zoophyta.*
VI. In which each polypus is inclosed in a horny or calcareous shell, and is not connected by a medullary axis.—*Eschara.*
VII. In which a solid axis is covered with a sentient flesh, from cavities in which the polypi issue.—*Ceratophyta.*
VIII. In which a stony axis or base serves for the receptacle of the polypi.—*Lithophyta.*
IX. In which the base is spongy, friable, or composed of fibres.—*Spongia.*

ANATOMY OF A COW.

Class 1st, order 2d, genus 8th, species ruminantia.

Fœtal state.

For the production of the fœtus in this animal, as well as in the human species, something is necessarily derived from the ovaria. The uterus of the cow has large cornua, in which a portion of the secundines is contained; consisting principally of the allantois, with the contained liquor. The muscular fibres of the uterus are plainly marked. Upon its internal surface are found a number of glandular bodies, which are formed by the termination of the uterine vessels. When the womb is in an impregnated state, a kind of mucilaginous liquor may be pressed out of these glandular bodies. These are called the papillæ of the uterus. The mouth of the womb (os uteri) is entirely closed by a mucilaginous substance, that is common to the females of all animals when in a state of pregnancy. The first of the proper membranes of the fœtus is the chorion; on the external surface of which are spread a number of fleshy bodies; called cotyledones, or placentulæ, which answer the same purpose with the placenta in the human subject. These, though indented among the papillæ, have no vascular connection with them.

The allantois, or allantoides, is the second membrane of the uterus. This is extremely fine and transparent; it is not an entire involucrum of the fœtus, but is chiefly lodged in the cornua uteri. In mares, bitches, and rabbits, it envelopes the amnios. In sheep and goats, the form and comparative extent of this membrane, are nearly the same as in the animal we are now describing, while in swine and in rabbits it covers still less of the amnios. A quantity of urine is commonly found in the sac, which this membrane forms, probably by the dilatation of the urachus, which is connected at its other extremity to the fundus of the bladder. This membrane is exceedingly vascular; its existence in the human female has been a subject of much dispute. See MIDWIFERY.

The third proper involucrum of the fœtus is the amnios. This membrane is thinner and firmer than the chorion. Ramifications of the umbilical arteries and veins are spread out upon it, by the terminations of which,

at its lateral parts, a liquor is secreted into the cavity of the membrane. This liquor is, in the first instance, in a small quantity; it afterwards increases; and again, towards the end of pregnancy, decreases. The amnios does not enter the cornua uteri.

We find in the fœtus of this animal two venæ umbilicales, the circulation of which is performed in the following manner. The blood from the placenta of the mother is conveyed into the capsula glissoniana, where it becomes blended with the blood of the vena portarum. Part of this blood proceeds immediately to the cava by the ductus venosus; the rest circulates through the liver. The whole is transmitted from the cava into the right auricle, whence part is sent by the foramen ovale into the left auricle: the rest passes directly into the pulmonary artery, through the right ventricle. A small portion of this last circulates through the lungs, while the greater part is conveyed immediately from the pulmonary artery through the medium of the canalis arteriosus into the descending aorta.

Adult state.

There are no dentes incisores in the upper jaw of this animal; but the gums are hard, and the tongue remarkably rough; its substance being covered by long sharp-pointed papillæ, which are turned towards the throat, for the purpose of retaining the received aliment. The œsophagus of this animal is composed of a double row of spiral fibres, which decussate each other. In common with all the ruminating animals, the cow has more than one stomach. Some of the ruminantia have two, some three; while the subject under examination has four stomachs, or rather ventricles; the first of these is the largest; it is vulgarly called the paunch; this lies upon the left side, and immediately receives the aliment. Upon the internal surface of this ventricle, there are a great number of small blunted processes, which give the whole a general roughness and considerable extent. By the force of the muscular coat of the paunch, aided by the gastric liquors, the food is in this cavity sufficiently macerated; after which it is returned through the œsophagus into the mouth, where it is now masticated. This process is what is called chewing the cud, or rumination. After rumination the food is sent down into the second stomach, into which the œsophagus opens directly, as well as into the first. This second stomach is smaller than the first; it is situated anteriorly: the cells on its internal surface cause it to assume the appearance of a honeycomb. Here the food is further macerated, and is hence protruded into the third; the interior surface of which forms a number of plicæ or folds; from this stomach it passes into the fourth, the structure and function of which greatly resemble the human stomach. This perhaps ought, in strict propriety, to be alone denominated the stomach. It is worthy of remark, that in consequence of the elaboration of the aliment in ruminating animals, much less food is required by them than by others, who have only one stomach. In the horse there is but one ventricle for the maceration of the ingesta, from which a liquor for nourishment is extracted, and the remainder discharged, by the anus, very little altered.

The intestinal canal of the cow is of considerable length; there is scarcely any difference in the diameters of the large and small guts. The cœcum is capacious and long; the spleen is attached to the diaphragm; the liver is not divided into so many lobes as in man; the vesica urinaria is of a pyramidal shape; it is exceedingly capacious; the cornua of the uterus are contorted in the form of a snail; the heart differs in form from that of man principally in having a more acute point, which point is composed only of the left ventricle; the aorta is properly, in this animal, divided into ascending and descending.

ANATOMY OF A DOMESTIC FOWL.

Class 2d, genus 4th, species gallinæ.

This animal, like all others of the same class, is oviparous. The œsophagus of this creature passes down its neck, inclining somewhat to the right side: it terminates in a large membranous sac, which is the ingluvies or crop, where the aliment is macerated and dissolved; then passing out, it proceeds down the remaining portion of the œsophagus into what has been called the ventriculus succentarius, formed by a continuation of the gullet, with more numerous glands. These glands separate a liquor, by which the food is still more diluted, before it enters the true stomach, gizzard, or ventriculus callosus.

The duodenum begins nearly at the same place where the œsophagus enters; the two orifices are however divided by means of a protuberance, called septum medium. The duodenum is chiefly situated in the right side; its two extremities are attached to the liver; the ductus choledochus enters near its termination, and discharges its contents into the gut, contrary to the course of the food.

The small intestines are of considerable length. At the termination of the ilia, there are two large cœca, one on each side proceeding in an ascending direction from the side of the rectum. The excretories of the urine have already been described, as discharging their contents into the cloaca. See general anatomy of the class aves.

The pancreas lies between the two folds of the duodenum; the spleen sends its blood into the vena portarum; the liver is divided into two equal lobes by a pellucid membrane. The principal peculiarity to be observed in the heart, is the want of the valvulæ tricuspides, and their place being supplied by one fleshy substance: the form and mechanism of the lungs are the same as in the other genera of the class. Cells are found in every part of the body, which communicate with those of the lungs; and, as before remarked, are filled with air, which even penetrates into the cavities of the bones. The trachea at its division is very much contracted. Hence, in part, the shrillness of voice peculiar to this class of animals. That birds are without diaphragm has already been remarked. In the animal we are now describing, the whole thorax and abdomen are divided by a longitudinal membrane, or mediastinum, attached to the lungs, pericardium, liver, stomach, and likewise covering the stomach and intestines; this is analogous to the omentum in the human species.

The lacteals pass from the intestines upon the mesenteric vessels; those of the duodenum run along the side of the pancreas; afterwards they arrive upon the cæliac artery: here they receive the lymphatics from the liver and gizzard, and shortly after another from the inferior part of the œsophagus. At the root of the cœliac artery they are joined by the lymphatics of the glands; and

near the same part by the lacteals of the small intestines. A particular branch passes from the rectum, which receives some small vessels from the kidneys at the root of the cœliac artery. The lymphatics of the inferior extremities appear to unite with those from the intestines. At the root of the cœliac artery the junction of the lymphatics forms a kind of net-work, from which arise two thoracic ducts, one lying on each side of the spine, which terminate near the angle formed by the jugular and subclavian veins. The ducts are joined by the lymphatics of the neck, and probably by those of the superior members or wings, at the place of their entrance into the jugulars. The chyle, it has already been observed, in all birds is like the lymph, transparent and colourless.

The kidneys lie in the hollow of the back-bone, from which the ureters pass into the cloaca. The testicles are placed on each side of the spine, and are remarkably large in this animal: the seminal vessels pass from these at first in a straight direction, but afterwards are convoluted, like the epididymis of the human subject. These convolutions partly supply the want of vesiculæ seminales; the coition however of these animals is very short; the vasa seminifera terminate in the penes, of which, in the cock, there are two. Birds in general are without prostrate gland. From the large size of the testes this animal is remarkably salacious, and is capable of impregnating many females. Impregnation is effected in the following manner: The racemus vitellorum of the female being analogous to the human ovaria, is attached by a membrane to the spine, which membrane is continued down to the uterus. The orifice of the womb is averse in respect to the ovaria; notwithstanding, by the force of the venereal orgasm, it turns round and grasps the vitellus: the substance from the racemus, in its passage through the duct, receives a gelatinous liquor, by which, with what it afterwards receives in the uterus itself, the white of the egg is formed. The shell is lined with a membrane, and in the larger end there is a bag filled with air, for which there is no outlet.

When the egg is completed, it is pushed out from the uterus, through an aperture at the side of the common cloaca. When the hen lays eggs that are not impregnated, the semen of the male has not been applied to the vitelli. These eggs appear to be complete, with the exception of a small black spot, which is that from which the rudiments of the chick are formed.

General view of the organs subservient to animal motions.

FIRST, OF THE SKELETON.

The bones of which the skeleton is composed are for the most part articulated, so as to form a whole. To this rule, however, there are exceptions. In birds and in quadrupeds, the bones which support the tongue are only connected by soft parts with the general skeleton. In those quadrupeds which have no clavicles, all the osseous parts of the anterior extremities are only attached by muscles; in other quadrupeds they are merely joined to the sternum by single clavicles, and by double ones in the class aves.

In fishes they are connected with the vertebral column by a bony girdle. In this class of animals the posterior extremities are generally free, and simply fixed in the muscular substance, while in other animals they have a firm connection with the rest of the skeleton through the medium of the pelvis.

There are three primary divisions of the skeleton; the head, the trunk, and the extremities.

The first is in no instance wanting. In serpents, and in some fishes, the extremities are totally wanting. In those fishes that are without ventral fins (apodes Linnæi), and in the cetacea among the mammalia (cete Lin.), the posterior extremities are wanting. The anterior extremities only are wanting in one species of lizard.

No vertebral animal has more than four extremities, unless we include the kind of wing which belongs to the flying-dragon, a small animal nearly similar to our lizard.

The trunk is formed by the vertebræ, ribs, and sternum; the number of the vertebræ is variable. The sternum is absent in serpents and fishes. The ribs are wanting in frogs, rays, sharks, and a number of cartilaginous fishes.

It is but a small number of the vertebral animals that are without coccyx: these are the ternate bats, and the frog kind. Several fishes have no neck. The false ribs are always posterior in quadrupeds. In birds they are both before and behind. In the crocodile, and some other animals, there are ribs which proceed from the sternum, but which do not join the vertebræ: others come from the vertebræ, and unite anteriorly with the corresponding ribs, without any intermediate sternum, as in the cameleon. The head is invariably placed at the anterior extremity of the vertebral column. It is divided into three parts, which, although they differ in relative proportions, are never wanting. These parts are, 1st, The cranium, in which the brain is contained, and in the partitions of which the cavities of the internal ear, and frequently those of the nose, are situated. 2. The face, which contains the orbits of the eyes, and the nasal cavities, and which terminates inferiorly by the upper jaw. 3. The lower jaw, which in all animals is moveable, even in the crocodile. The upper jaw is immoveable in man, in quadrupeds, and in some reptiles, as the tortoise, the crocodile, and others; it is more or less moveable in birds, serpents, and fishes. The extremities when perfect, are divided into four parts: those which belong to the anterior members are the shoulder, the arm, the fore-arm, and the hand; those of the posterior are the hip, the thigh, the leg, and the foot. These distinctions do not obtain among fish, whose extremities are merely formed of osseous rays, or bones, constituted like a fan, and articulated to parts corresponding with the shoulder or hip. The shoulder is formed of the scapula placed against the back, and the clavicle attached to the sternum. The last is wanting in some quadrupeds and the cetacea; it is double in birds, tortoises, frogs, and many lizards. Where extremities exist, the scapula is always found. The arm is constituted by one bone; the fore-arm has almost always two; even when this last part consists of only one bone, there generally appears a kind of separating furrow. The hand, as it respects the number of its bones, considerably varies, but the osseous portions of which it consists always form a carpus, metacarpus, and fingers. This is the case even in birds, the fingers of which are enveloped in a skin covered by feathers. This

organization likewise obtains in the cetacea, in which the whole anterior member is reduced to the figure of an oar or fin.

The various parts of the skeleton are usually disposed with a strict attention to symmetry; so that when divided by a longitudinal section, the two halves are counterproofs of each other. In one kind of fish, however, called pleuronectes, which comprehends soles, plaice, turbots, &c. the head is so constituted, that the two eyes and the two nostrils are on the same side.

It may be proper to remark, before we conclude this general account of the skeleton, that although an animal of one class may appear similar to that of another, the resemblance is merely outward; and affects the skeleton, not in the number or arrangement of its bones, but merely in its total proportions. Bats, for instance, appear to have wings; but an anotomical examination demonstrates these to be in reality hands, the fingers of which are merely somewhat lengthened. In like manner, although dolphins appear to have fins, composed of an entire piece, we find under the external covering all the bones that compose the anterior extremities of the other mammalia, short, and nearly immoveable.

Of the forms and actions of muscles.

While the form and number of bones, and the mode in which they are articulated, determine the number, kind, and direction, of motions they are capable of, the number and situation of the muscles determine the number, kind, and direction, of the motions that are actually performed.

Muscles are attached to the bones by tendons. The tendons, like the muscles, are composed of fibres, but they are more close and firm, and have a silver whiteness. The form of the tendon varies as much as that of the muscle. Heavy birds, that walk much, have the tendons of their limbs ossified at a very early period. The same thing takes place in the jerboa, and other animals, that always leap with their posterior extremities.

The tendons of the crustacea and insects are frequently articulated with the scaly case they have to move, in the same manner as one bone is articulated with another; with this case they are connected by a membranous ligament. This structure is particularly observable in the great claws of cray-fish.

The tendons of the mollusca are not perceptible; but this is in consequence of the tendinous and fleshy parts, both having the same colour. The muscles are divided into simple and compound: the first comprehend those in which the fibres have one direction only; the most common are the ventriform, the fibres of which are nearly parallel, and compose a long bundle of a round shape; their fleshy portions swell in the centre, which is called the belly of the muscle. The second kind of simple muscle is flat, and has parallel fibres. These form a sort of fleshy membrane, which, instead of terminating in small tendons, ends by aponeurosis, or a kind of tendinous membrane.

In the action of muscles it appers that the elementary fibres, all individually, exercise the same power at the moment of contraction; but the sum total of force is directed by the manner in which these fibres are disposed, or the situation of the whole muscle. It is obvious then, that in either kind of these simple muscles above described, the total action is equal to the sum of all the particular actions, which however is not the case with the two other kinds of simple muscles, the radiated and penniform. Muscles are said to be radiated, when the fibres of which they are composed are disposed like the radii of a circle, which, proceeding from a base of a greater or less magnitude, incline towards each other, and are inserted in a small tendon.

Penniform muscles have their fibres arranged in two rows, which unite in a middle line, and form with each other angles more or less obtuse, assuming the appearance of the feathers of a quill. Their tendon is a prolongation of this central line.

In these two last kinds of muscles the resulting force must necessrily be less than the collective sum of the component forces: it is only equal to the sum of the diagonals of the parallelograms, which are formed from every two fibres that unite in the production of one angle.

Compound muscles are produced by the union of several in one common tendon. Sometimes these uniting muscles are of a similar nature: at others the compound muscle is formed by an assemblage of various kinds, as the radiated, the ventriform, and others.

There are some muscles with only one belly with divided tendons; others have several fleshy parts and tendons interlaced in various ways. These last may be denominated complicated muscles.

Muscular origin and insertion may be considered as of eight distinct kinds. A muscle, or muscles, may be destined to compress the soft parts contained in a cavity, which is then enveloped by the muscular fibres in different directions, in the form of membranes or bands. Such is the arrangement in the abdominal muscles and diaphragm of the human species; such is the disposition of the muscles of slugs, other mollusca, and naked worms, which can contract themselves in every direction. When a number of such muscles act in conjunction, it is for the purpose of expelling some matter from the body, as excremement, or ova; their more usual action however is alternate, and then their effect is to increase one of the diameters of the cavity they surround, and diminish the other. Thus, for example, during every inspiration the abdomen becomes wider and shorter, while exactly the contrary takes place on each expiration. In like manner slugs and leeches lengthen and shorten themselves, by first moving their annular, and then their longitudinal muscles.

Upon this principle likewise, those muscles act which are destined to lengthen or shorten, and to relax or compress, any soft part; such as the tongue of man, or the horns of snails. The heart, the arteries, the intestines and other organs, are furnished with muscles of this kind.

Some muscles are calculated to enlarge or diminish a soft aperture; of these some surround the orifice as the sphincters; others are inserted more or less directly in the margins of the apertures. When they are uniformly extended round the orifice, such orifice preserves its figure, and is always dilated or contracted in the same manner. The eyelid of the moon-fish, and the anus of the snail, present examples of this species of muscular motion. When these muscles are inserted in different directions, the form of the aperture is very variable; as for

instance, in the lips of man. The expressive variety of the human physiognomy arises in a great measure from the great mobility of this part.

Another employment of the muscles is to extend and fold back in the manner of curtains, membranes that furnish coverings to certain parts; such as the eyelids of man, quadrupeds, and birds. When such muscles are in the bodies of these membranes, their descriptions are the same as above described; but when their situation is external, they form complicated pulleys.

Again, muscles are employed in the act of turning or rolling a globular mass, which, although free, is supported on every side, as the human eye in the orbit, or the mouth of a snail in its head. The muscles surround such parts in the form of a hoop, and the body which they move is turned to that part in which the muscle contracts with most vigour.

These four modes of action may all be referred to that of the sphincters or circular muscles.

The following mode in which the muscles perform their action may be compared to the action of ropes, drawing a resisting object; the muscular fibres pulling in the direction in which the motion of the part operated upon is to be performed; or if the muscles diverge, an equal quantity of action is produced on either side, and the resulting force is employed to still more advantage. Of the first kind of action, the sterno-hyoideus and genio-hyoideus form examples, and the motions of the mylo-hyoideus and scapulo-hyoideus are instances of the second.

When the bone on which the muscular agency is displayed, cannot be elevated or depressed all at once, it must then be regarded as a lever, the articulation affording the fulcrum.

When the articulation is between the two extremities, and the muscles are situated at one of them, the bone forms a lever of the first rank; such is the case in the mandible of the cray-fish; an example of a similar kind is likewise furnished by the olecranon and os calcis, with their respective muscles; but the most remarkable is, the tibia of those birds called grebes and divers; the long apophysis of which, raised above the knee, serves as a substitute for the patella.

But the most common case of muscular attachment is, that in which the articulation is at one extremity of the bone; then the most favourable position of the muscle is, when it originates from another bone parallel to that which it has to move, or when it forms with the latter only a very small angle; such is the case with the intercostales, interspinales, and intertransversi; and the muscles which draw together bones of a fan-like shape, as the wings of the flying dragon.

The muscles which close the mouth of man and the bill of birds may be also compared to the preceding; these however are inserted nearer to the point of support, and by consequence their force is diminished.

The last and most usual mode of insertion is, when a muscle united with one bone is inserted into another which last is articulated with the first, and may be extended so as to form together a right line, or bent into a very small angle; this mode is the most disadvantageous, on account of the extreme obliquity of the insertion when the moveable bone is extended, and because of its proximity to the fulcrum; this inconvenience, however, is in some measure obviated by the heads of bones, or enlargements of their articular extremities; so that the tendons, turning round a convexity in order to be inserted below it, form more obtuse angles.

It was necessary that the fulcrum of motion should be near, to prevent the members from being inordinately large, and likewise for the production of a ready and complete flexion, as the muscular fibre loses only a determinate fraction of its length in contraction. Examples are afforded of muscles inserted at a great distance from the fulcrum: birds have one which extends from the top of the shoulder near to the carpus; this however happens because all the angle formed by the radius and ulna is, in these animals, occupied by a membrane intended to augment the surface of the wing.

It is in consequence of the small contraction of the muscular fibre, that the short bones in which complete inflexion is required, are moved by muscles attached to bones at a distance: the vertebræ and phalanges of the fingers are in this situation. Muscles extended from one to the other of these small bones could not have produced a sufficient flection: besides, in the phalanges they would have made the fingers disproportionately thick: it is also necessary that the tendons of these muscles be fixed down to the bones over which they pass; otherwise whenever the phalanges were bent, the muscles and tendons would remain in a straight line like the string of a bow; hence the utility of the carpal ligaments, the sheaths, and perforations. In animals that have but three phalanges, as in man, there is but one perforation; but birds, which have one toe with four and another with five phalanges, have two perforations and consequently three muscles,—one perforated, one perforating and perforated, and one perforating.

Those vertebræ which have much motion, for example, those of the neck in birds, and of the tail in quadrupeds, have likewise very distant muscles; but their long tendons are enclosed in sheaths, which continue to bind them, until they arrive opposite the place of termination.

External form as an indication of the nature of the sentient organization.

In the general description which we have already given of the skeleton, the head of vertebral animals was said to be capable of division into three parts, viz. the cranium, face, and inferior maxilla; as it relates however to the sentient organization, the head will only admit of two primary divisions: the cranium, containing the brain; and the face, in the cavities of which are lodged the organs of sight, smell and taste. The organs of hearing are situated on the sides of the cranium. A capacious cranium and a small face are the indices of a large brain and less developed senses of smell and taste.

The relative proportion of the cranium and the face, also indicates a greater or less degree of perfection in those faculties which are generally denominated intellectual or reflective, compared with the external or sensitive. In man the cranium is relatively the largest, and the face the smallest; and animals, as they depart from these proportions, become in the same ratio more stupid and ferocious. To this general rule, however, there are some exceptions. See the article Physiognomy.

One of the most simple means of ascertaining these proportions is by means of the facial line of Camper, and the angle which it forms with the basis of the cranium. The facial line is supposed to pass in contact with the upper incisores teeth, and the most prominent part of the forehead; and the basilar line of the cranium is that which bisects longitudinally a plane passing through the external openings of the ear, and along the lower edge of the anterior aperture of the nostrils. In proportion as the forehead projects or the cranium is enlarged, the angle made by these lines must necessarily increase; on the contrary, as the cranium diminishes in size, or the forehead recedes, the facial line will incline further back and diminish the angle. In man the facial angle is wider than in any other animal, and it becomes always more acute in the different animals as they are removed from man.

In the European, it is 85°; negro, 70°; orang-outang, 67°; pug-dog, 35°; polecat, 31°, &c.

Still more important relations, however, are discovered by means of a vertical and longitudinal section of the head. In the European the area of the section of the cranium is nearly four times as large as that of the face, exclusive of the inferior maxilla. In the negro the face is increased about one-fifth. The proportion of the cranium is still less in the orang-outang; in the sapajous the face is nearly one-half of the cranium; in most of the carnivora it is nearly equal. In the rodentia, pachydermata, ruminantia, and solipedia, the area of the section of the face is larger than that of the cranium. Of the rodentia, the hare and marmot have it one-third larger. In the porcupine it is more than double, a little more than double in hogs, nearly triple in the hippopotamus, and almost quadruple in the horse. (N. B. The above proportions are given on the authority of M. Cuvier.)

These remarks are particularly interesting in relation to the mammalia order of animals, as in these the cavity of the cranium is occupied entirely by brain; so that the description of the osseous part, indicates pretty accurately the external form of the whole encephalon.

The proportion which the cranium bears to the face in birds, does not authorise the same inductions as in the mammalia; and with respect to reptiles and fishes (the remaining class of vertebral animals) no important inferences can be made from the magnitude and form of the cranium, as the brain only occupies a small part of its cavity. In the nervous system of the mollusca, crustacea, and insects, the utmost irregularity obtains; and it has already been stated that in the zoophytes, which occupy the lowest rank in the scale of animal life, a distinct sentient organization has not hitherto been detected. For the internal organization and functions of the nervous system, consult the article Physiology.

COMPARISON, in rhetoric, a figure that illustrates and sets off one thing, by resembling and comparing it with another, to which it bears a manifest relation and resemblance, as in the following figure in Shakspeare:

> She never told her love,
> But let concealment, like a worm,
> Feed on her damask cheek: she pined in thought,
> And sat like Patience on a monument,
> Smiling at Grief.

COMPASS, or mariner's compass, an instrument by which the ship's course is determined. See Magnetism, and Navigation.

Compasses, or pair of compasses, a mathematical instrument for describing circles, or measuring figures. See Instruments Mathematical.

COMPENSATION, in the civil law, a sort of right, whereby a debtor, sued by his creditor for the payment of a debt, demands that the debt may be compensated with what is owing him by the creditor, which, in that case, is equivalent to payment.

COMPERTORIUM, in the civil law, signifies a judicial inquest made by delegates to search out and relate the truth of a case.

COMPITALIA, or Compitalitia, in Roman antiquity, feasts instituted by Servius Tullius in honour of the Lares. These feasts were observed on the 12th of January and 6th of March. Tarquinius Superbus, consulting the oracle upon the subject of the sacrifices to be offered on that occasion, was answered that he should offer heads to Lares: for which reason, the Romans presented the heads of young children in sacrifice to those deities. But Junius Brutus ordered poppy-heads to be offered in their stead. Macrebius relates, that they satisfied the Lares, by offering the images of men and women made in straw; and that for each slave in their family, they threw in so many bales of wool.

COMPLEMENT, in astronomy, the distance of a star from the zenith: or the arch comprehended between the place of the star above the horizon and the zenith.

Complement, in geometry, is what remains of a quadrant of a circle, or of 90°, after any certain arch has been taken away from it. Thus, if the arch taken away be 40°, its complement is 50: because 50+40=90. The sine of the complement of an arch is called the cosine, and that of the tangent the co-tangent, &c.

Complements in a parallelogram, are the two smaller parallelograms made by drawing two right lines through the diagonal, and parallel to the sides of the parallelogram.

In every parallelogram, these complements are equal. See Mechanics.

COMPLEX terms, or ideas, in logic, are such as are compounded of several simple ones. Complex ideas are often considered as single and distinct beings, though they may be made up of several simple ideas, as a body, a spirit, a horse, a flower; but when several of these ideas of a different kind are joined together, which are usually considered as distinct single beings, they are called a compound idea, whether these united ideas be simple or complex. Complex ideas, however compounded and recompounded, though their number is infinite, and their variety endless, may be all reduced under three heads, modes, substances, and relations.

Complex proposition, is either that which has at least one of its terms complex; or such as contains several members, as casual propositions; or it is several ideas offering themselves to our thoughts at once, by which we are led to affirm the same thing of different objects, or different things of the same object. Thus, God is infinitely wise, and infinitely powerful. In like manner, in the proposition, Neither kings nor people are exempt from death.

COMPLEXUS, in anatomy, a broad and pretty long muscle, lying along the back part and side of the neck. See ANATOMY.

COMPOSITE NUMBERS, are such as can be measured exactly by a number exceeding unity; as 6 by 2 or 3, or 10 by 5, &c. so that 4 is the lowest composite number. Composite numbers between themselves, are those which have some common measure besides unity; as 12 and 15, as being both measured by 3.

COMPOSITE ORDER. See ARCHITECTURE.

COMPOSITION, in grammar, the joining of two words together; or prefixing a particle to another word, to augment, diminish, or change its signification.

COMPOSITION, in logic, a method of reasoning, by which we proceed from some general self-evident truth, to other particular and singular ones.

COMPOSITION, in music, the art of disposing musical sounds into airs, songs, &c. either in one or more parts, to be sung by a voice, or played on instruments.

Under composition are comprehended the rules, 1. Of melody, or the art of making a single part; that is, contriving and disposing the simple sounds, so as that their succession and progression may be agreeable to the ear. 2. Of harmony, or the art of disposing and concerting several single parts together, so as that they make one agreeable whole. It may be proper to observe here, that melody being chiefly the business of the imagination, the rules of its composition serve only to prescribe certain limits to it, beyond which the imagination, in searching out the variety and beauty of airs, ought not to go; but harmony being the work of the judgment, its rules are more certain and extensive, and more difficult in practice.

COMPOSITION, in painting, consists of two parts, invention and disposition; the first of which is the choice of the objects which are to enter into the composition of the subject the painter intends to execute, and is either simply historical or allegorical. See PAINTING.

COMPOSITION, in commerce, a contract between an insolvent debtor and his creditors, by which the latter accept of a part of the debt in compensation for the whole, and give a general acquittance accordingly.

COMPOSITION, in printing, commonly termed composing, the arranging of several types, or letters, in the composing-stick, in order to form a line; and of several lines ranged in order in the galley, to make a page; and of several pages to make a form. Generally the composing-stick is made of iron, sometimes of wood; more or less in length or depth, according to the page to be composed, or the fancy of the compositor. It has two sliding-pieces, fastened by means of a nut and screw, which are slipped forwards or backwards, according to the space which the lines, notes, &c. are to take up, or the compositor thinks proper. The composing stick ordinarily contains seven or eight lines of a middle-sized letter: these lines, when set, are taken out by means of a thin slip of brass called a rule, and disposed in the galley: then others are composed, until a page is formed, which being done, it is tied up and set by; the rest of the pages that make up a sheet, being prepared in the same manner, are carried to the imposing or correcting-stone, and being there ranged in order, they are disposed in an iron frame, fitted with wooden furniture: then the quoins being stuck in, the chace, or frame, is put in the press, in order to their being printed. See PRINTING.

COMPOSITION of motion, is an assemblage of several directions of motion, resulting from several powers acting in different, though not opposite, directions. See MECHANICS.

COMPOSITION of proportion, is the comparing the sum of the antecedent and consequent, with the consequent in two equal ratios; as suppose, 4 : 8 : : 3 : 6, they say, by composition of proportion, 12 : 8 : : 9 : 6. The same holds of the sum of the antecedent and consequent, compared with the antecedent: thus we likewise say 12 : 8 : : 9 : 6. There is a great difference between composition of proportion by addition and by multiplication. See PROPORTION.

COMPOST, in husbandry and gardening, several sorts of soils, or earthy matters, mixed together, in order to make a manure, for assisting the natural earth in the work of vegetation, by way of amendment or improvement.

COMPOSTO, in music, means compounded or doubled, as a fifteenth is an octave doubled, or an octave is compounded of a fifth and a fourth.

COMPOUND FLOWER; one consisting of several distinct lesser flowers, or corollulæ, each furnished with a style, stamina, &c. The corollulæ are of two kinds, viz. tubulated and ligulated: the tubulated are always furnished with a campanulated limb, divided into four or five segments; whereas the ligulated corollulæ have only a flat, linear limb, terminated by a single point, or by a broader extremity, divided into three or five segments. The plants with compound flowers are extremely numerous, forming a class by themselves, called by Linnæus, syngenesia.

COMPOUNDS, PRIMARY, in chemistry. If the science of chemistry had made sufficient progress, the division would comprehend all the primary compounds which the simple combinable substances are capable of forming. These might all be classed under six heads. Three of these would consist of compounds which oxygen forms with the other simple substances; for all these compounds are either combustible oxyds, products, or supporters. The fourth class would consist of the compounds which the simple combustibles form with one another and with the metals; the fifth class, of the combinations of the metals with one another; and the sixth would consist of the combinations of the simple incombustibles with the combustibles and the metals. But in the present imperfect state of the science, the advantages attending this arrangement would not compensate for the violence of the changes which it would introduce. It would oblige us to classify substances together which have always been considered as distinct, and to separate many bodies which have hitherto been always grouped together. Besides, we should be forced to omit a number of substances which are still undecompounded, and which are not the less important because they cannot with propriety be introduced among the simple substances. For these reasons the primary compounds may be arranged under the five following heads:

1. Alkalies. 2. Earths. 3. Oxyds. 4. Acids. 5. Compound combustibles.

COMPOUNDS, SECONDARY. Many of the primary compounds are susceptible of forming combinations with each other. Thus acids combine with alkalies, with earths,

and with metallic oxyds, and form compounds called salts; the earths combine with the fixed alkalies, and form glass; oils combine with alkalies, and form soaps. To these is given the name of secondary compounds, which, as far as we are at present acquainted with them, may be arranged under the five following classes. 1. Combinations of earths with each other, and with metallic oxyds. 2. Combinations of earths with alkalies. 3. Combinations of acids with alkalies, earths, and metallic oxyds. 4. Combinations of sulphureted hydrogen with alkalies, earths, and metallic oxyds. 5. Combinations of oils with alkalies, earths, and metallic oxyds.

COMPREHENSION, or SYNECDOCHE, a trope or figure in rhetoric, which puts the name of the whole for a part, or of a part for the whole; a general for a particular of the same kind, or a particular for a general. By this trope a round and certain number is often set down for an uncertain one.

COMPRESS, in surgery, a bolster of soft linen cloth, folded in several doubles, frequently applied to cover a plaster, in order not only to preserve the part from the external air, but also the better to retain the dressings, or medicines. See SURGERY.

COMPTONIA, a genus of the monoecia triandria class and order. The male cal. is an ament two-leaved; cor. none; anthers two-parted. The female is also an ament, cal. six-leaved; cor. none; styles two; nect. ovate. There is one species, a shrub of North America, named after bishop Compton, eminent for his taste in botany.

COMPULSOR, an officer under the Roman emperors, despatched from court into the provinces, to compel the payment of taxes, &c. not paid within the time prescribed. These were charged with so many exactions, that Honorius cashiered them.

COMPUTATION, in law, is used with respect to the true account or construction of time: so understood, as that neither party to an agreement, &c. may do wrong to the other; and that the determination of time be not left at large, or taken otherwise than according to the judgment and intention of law.

If a lease is engrossed, bearing date January 1, 1806, to have and to hold for three year from henceforth, and the lease is not executed till the 2d of January; in this case the words 'from henceforth' shall be accounted from the delivery of the deed, and not by any computation from the date. And if the lease be delivered at four o'clock in the afternoon on the said second day, it shall end the first day of January, in the third year; the law in such computations, rejecting all fractions or divisions of the day.

COMPUTO, in law, a writ to compel a bailiff, receiver, or accountant, &c. to deliver up his accounts. The same lies for executors of executors, and against the guardian in socage for waste made in the minority of the heir.

CONCENTRATION, in general, signifies the bringing things nearer a centre. Hence the particles of salt in sea-water are said to be concentrated, that is, brought nearer each other, by evaporating the watery part: thus, also, wine is said to be concentrated, when its watery parts are separated in the form of ice by frost.

CONCENTRIC, in mathematics, something that has the same centre with another: it stands in opposition to excentric.

The method of Nonius for graduating instruments consists in describing with the same quadrant 45 concentric arches, dividing the outermost into 90 equal parts, the next into 80, &c.

CONCERT, a musical performance in which any number of practical musicians, either vocal or instrumental, or both, unite in the exercise of their respective talents. The concerts of the ancient Greeks were executed only in the unison or octave.

CONCERTO, (Ital.) a composition expressly written for the display of some particular instrument, with accompaniments for the band.

CONCERTANTE, (Ital.) a concerto for two or more instruments, with accompaniments for a band.

CONCERTINO, (Ital.) the principal instrument in a concerto or concertante; as oboe concertino, the principal hautboy.

CONCERTATO intimates the piece of music is composed in such a manner, as that all the parts may have their recitativos, be it for two, three, four, or more voices or instruments.

CONCESSION, in rhetoric, a figure, whereby something is freely allowed, that yet might bear dispute, to obtain something that one would have granted to them, and which he thinks cannot fairly be denied; as in the following concession of Dido, in Virgil:

> The nuptials he disclaims, I urge no more:
> Let him pursue the promis'd Latin shore.
> A short delay is all I ask him now;
> A pause of grief, an interval from woe.

CONCHA, in anatomy, the larger cavity of the external ear, situated before the meatus auditorius, or passage into the internal ear. See ANATOMY.

CONCHOID, in geometry, the name of a curve, given it by its inventor, Nicomedes, and thus generated.

Draw the right line QQ (Plate XXX. Miscel. fig. 16.), and AC perpendicular to it in the point E; and from the point C draw right lines CM, cutting the right line QQ in Q; and make QM = QN, AE = EF, viz, equal to an invariable line: then the curve in which are the points M, is called the first conchoid; and the other, in which are the points N, the second; the right line QQ being the directrix, and the point C the pole: and from hence it will be very easy to make an instrument to describe the conchoid. The line QQ is an asymptote to both the curves, which have points of contrary flexion. If QM = AE = a, EC = b, MR = EP = x, ER = PM = y; them will $a^2 b^2 - 2 a^2 b x + a^2 x^2 = b^2 x^2 - 2 b x^3 + x^4 + x^2 y^2$, and express the nature of the second conchoid; and $x^4 + 2 b x^3 + y^2 x^2 + b^2 x^2 = a^2 b^2 + 2 a^2 b a + a^2 x^2$, the nature of the first; and so both these curves are of the third kind.

This curve was used by Archimedes and other ancients, in the construction of solid problems; and sir Isaac Newton says that he himself prefers it before other curves, or even the conic sections, in the construction of cubic and biquadratic equations, on account of its simplicity and easy description. See sir Isaac Newton's Universal Arithmetic.

CONCLAMATION, in Roman antiquity, a custom of calling the dead party by his name for eight days

successively; on the ninth, concluding him past all hopes of recovery, they carried him forth and buried him.

CONCLAVE, the place in which the cardinals of the Romish church meet, and are shut up, in order to the election of a pope. The conclave is a range of small cells, ten feet square, made of wainscot: these are numbered, and drawn for by lot. They stand in a line along the galleries and hall of the Vatican, with a small space between each. Every cell has the arms of the cardinal over it. The conclave is not fixed to any one determinate place, for the constitutions of the church allow the cardinals to make choice of such a place for the conclave as they think most convenient; yet it is generally held in the Vatican. The conclave is very strictly guarded by troops: neither the cardinals, nor any person shut up in the conclave, are spoken to, but at the hours allowed of, and then in Italian or Latin; even the provisions for the conclave are examined, that no letters be conveyed by that means from the ministers of foreign powers, or other persons who may have an interest in the election of the pontiff.

After this assembly has continued three days, they are only allowed one dish for one meal; and after five days, only bread and water: but this rule is not very religiously observed.

CONCOCTION. See Physiology.

CONCORD, in grammer, that part of construction called syntax, in which the words of a sentence agree; that is, in which nouns are put in the same gender, number, and case; and verbs in the same number and person with nouns and pronouns.

Concord, in common law, the agreement between parties, who intend to levy a fine of lands to one another, how and in what manner they shall pass.

Concord, in music, an union of two or more sounds, which by their harmony produce an agreeable effect upon the ear. Unisonance being the relation of equality between the pitch of two or more sounds, all unisons are considered by most theorists as concords in the first degree. But an interval being a difference of pitch, or a relation of inequality between two sounds, will form a concord or discord, according to the circumstances of that particular relation. Of concords there are two kinds, the one called perfect, the other imperfect; perfect concords consist of the fifth and eighth, imperfect concords of the third and sixth. The imperfect concords have also another distinction; that of the greater and lesser third and sixth. The concords are again divided into consonant and dissonant. The consonant concords are the perfect concord and its derivatives; every other is a dissonant concord. We apply the word concord also to the state of an instrument in respect of its tuning, as also to the agreement of two or more voices: as when we say "That instrument is not in concord," or "not in tune;" "Those voices do not concord," or "do not harmonise and agree."

CONCORDANT verses, are such as have several words in common, but which by the addition of other words convey an opposite or at least a very different meaning; as,

Et { canis / lupus } in sylva { a atur / nutritur } & omnia { servat. / vastat.

CONCORDAT, in the canon law, a covenant or agreement in some beneficiary matter, as relating to a resignation, permutation, or other ecclesiastical cause. This word is used absolutely among the French for an agreement between pope Leo I. Francis I. of France, for regulating the manner of nominating to benefices.

CONCRETE, in logic, is used in contradistinction to abstract; for example, when we consider any quality, as whiteness, inhering in any subject, as suppose in snow; if we say the snow is white, then we speak only of whiteness in the concrete: but if we consider whiteness by itself, as a quality that may be in paper, in ivory, and in other things, as well as in snow, we are then said to consider, or to take, it in the abstract.

CONCRETIONS, morbid. Hard substances occasionally make their appearance in different parts of the animal body, both in the solids and in the cavities destined to contain the fluids. In the first case, they are usually denominated concretions or ossifications; in the second, calculi. The knowledge of these bodies is of importance both to the physiologist and physician. Their formation is an irregularity in the animal economy, and is likely therefore to throw light upon its functions; for we succeed best in detecting the secrets of nature when she deviates from that regularity which she usually follows. They often produce the most excruciating diseases; and the sufferings of the patient can only be effectually relieved by removing their cause. The different animal concretions at present known may be divided into five classes:

1. Ossifications.
2. Intestinal concretions,
3. Biliary calculi, } See Calculi.
4. Urinary calculi, }
5. Gouty concretions.

I. Ossifications. All the concretions which make their appearance in the solids of the animal body may be comprehended under this title with propriety; because they have all a close resemblance to bone, being composed of similar constituents. The following are the most remarkable of these concretions.

1. Pineal concretions. It is well known to anatomists that small concretions like sand are often lodged in that part of the brain called the pineal gland. It was suspected from analogy that they consisted chiefly of phosphat of lime; but Dr. Wollaston was the first who examined them chemically, and proved the truth of this opinion. He dissolved some of the sand in nitric acid, and evaporated the solution; small crystalline needles made their appearance, indicating the presence of phosphat of lime.

2. Salivary concretions. Small concretions occasionally make their appearance in the salivary glands, especially the parotid and sublingual. From the experiments of Wollaston and Fourcroy, we learn that the basis of these concretions is phosphat of lime united to a membraneous substance, which retains the shape of the concretion after the solution of the phosphat. This at least was the case in a small salivary calculus which we examined. The same chemists ascertained that the tartar of the teeth is phosphat of lime.

3. Pancreatic concretions. The hard substances sometimes found in the pancreas are said to be of the same na-

ture with those of the salivary glands. The assertion, we presume, is merely from analogy.

4. Pulmonary concretions. Many people subject to cough, or threatened with consumption, occasionally cough up small rounded white concretions. It is very common to find the lungs of such persons filled with similar bodies. We examined some of these bodies coughed up by a consumptive patient, and found them composed of phosphat of lime united to a thick membraneous substance, which retained the form of the concretion. The same result had been obtained long before by Fourcroy.

5. Hepatic concretions. The liver also is sometimes full of similar bodies. The shape of the hepatic concretions, as far as our observations go, is more irregular, and we have seen them of greater size, than the pulmonary concretions. By analysis, their composition is the same as that of the last species.

6. Concretions in the prostate. From the experiments of Dr. Wollaston, we learn that the concretions which sometimes form in the prostate gland have likewise phosphat of lime for their basis.

7. The extremities of the muscles and the larger blood-vessels sometimes harden, and assume the appearance of bone. It is believed that this change is a real ossification, or that these bodies are converted into real bone. We do not know whether any such ossifications have been analysed.

II. Concretions, intestinal. Concretions of very considerable size are sometimes found lodged in the stomach and intestines; seldom indeed in the human body, but more frequently in some of the inferior animals. Some of these bodies have acquired great celebrity under the name of bezoars; but their medical virtue, at least in this country, has long ago sunk to its just level. We are in possession of a chemical analysis of only a very small number of such concretions; even their figure and external characters have been but imperfectly described.

1. Of the horse. Two concretions, taken from the intestines of the horse, have been analysed; the first by Fourcroy, the second by Bertholdi; and both of them were composed of the same constituents. The first was of a grey colour, round, and weighed five pounds. It was radiated or crystallized in its structure. In the centre were several cavities filled with vegetable matter. It was insoluble in cold, but slightly soluble in boiling water. It was composed almost entirely of phosphat of magnesia and ammonia. The second was brownish-grey, round, and above four inches in diameter. Its specific gravity was 1,670. It was composed of eight concentric strata, all crystallized. In the centre there was found a small plate of iron. Its constituents were

18.0	magnesia
26.0	phosphoric acid
3.2	ammonia
46.0	water
4.0	animal matter
97.2	

2. Bezoars. The substances called bezoars, are supposed to be concretions formed in the stomach or intestines of different graminivorous animals. They are brought to Europe from India and America, and vary exceedingly both in their appearance and properties. To attempt a description would be useless, till we know more precisely the animals in which they are formed, and how many different animals yield them. Dr. Pearson analysed one specimen, and found it entirely composed of vegetable matter. See Calculi, and Bezoar.

III. Concretions, gouty. It is well known that concretions occasionally make their appearance in joints long subject to gout. These concretions, from their colour and softness, have received the name of chalkstones. They are usually small, though they have been observed of the size of an egg. It had long been the opinion of physicians that these concretions were similar to the urinary calculi. Of course, after the discovery of uric acid by Scheele, it was usual to consider the gouty chalkstones as collections of that acid. They were subjected to a chemical analysis by Dr. Wollaston, in 1797, who found them composed of uric acid and soda.

Gouty concretions are soft and friable. Cold water has little effect upon them; but boiling water dissolves a small portion. If an acid is added to this solution, small crystals of uric acid are deposited on the sides of the vessel.

These concretions are completely soluble in potash, when the action of the alkaline solution is assisted by heat.

When treated with diluted sulphuric or with muriatic acid, the soda is separated; but the uric acid remains, and may be separated by filtration. The liquid, when evaporated, yields crystals of sulphat or muriat of soda, according to the acid employed. The residuum possesses all the characters of uric acid. When distilled it yields ammonia, prussic acid, and the acid sublimate of Scheele. When dissolved in a little nitric acid, it tinges the skin of a rose colour, and when evaporated, leaves a rose-coloured deliquescent residuum. It is soluble in potash, and may be precipitated by any acid and by ammonia; first in the state of a jelly, and then breaking down into a white powder.

When uric acid, soda, and a little warm water, are triturated together, a mass is formed, which, after the surplus of soda is washed off, possesses the chemical properties of gouty concretions.

COND, Con, or Conn, in the sea-language, to guide or direct the ship to her right course, by giving directions to the man at the helm how to steer.

CONDENSER, a pneumatic engine or syringe, whereby an uncommon quantity of air may be crowded into a given space; so that sometimes ten atmospheres, or ten times as much air as there is at the same time in the same space without the engine, may be thrown in by means of it, and its egress prevented by valves properly disposed.

It consists of a brass cylinder, wherein is a moveable piston; which being drawn out, the air rushes into the cylinder, through a hole provided on purpose; and when the piston is again forced into the cylinder, the air is driven into the receiver through an orifice, furnished with a valve to hinder its getting out. See Pneumatics.

CONDERS, a term used in the herring fishery, for people who stand on cliffs or eminences near the sea-coast, to direct the fishermen which way the shoal of herrings passes; their course being more conspicuous to

those who stand on high cliffs ashore, than to those on board the vessels.

CONDITION, in the civil law, a clause of obligation stipulated as an article of a treaty or contract; or in a donation of testament, legacy, &c.: in which last case a donee does not lose his donative, if it is charged with any dishonest or impossible conditions. The conditions under which a donation can be made, are distinguished into three kinds: 1. The casual, which depends merely on chance; 2. The potestative, which is absolutely in our power; and, 3. The mixed condition, which is compounded of the other two.

CONDITION, in common law, a restraint annexed to a thing, so that by the non-performance the party to it shall sustain loss, and by the performance receive advantage; or it is a restriction of men's acts, qualifying or suspending the same, and making them uncertain whether they shall take effect or not. Also it is defined to be, what is referred to a contingency, which may or may not take place.

CONDITIONAL SYLLOGISM, in logic, a syllogism where the major is a conditional proposition. Thus,

If there is a God, he ought to be worshipped:
But there is a God;
Therefore he ought to be worshipped.

The Arminian divines maintain, that all the decrees of God relating to the salvation and damnation of man, are truly conditional; and the calvinists that they are absolute. The science of conditionals, that is, of conditional truths, is the knowledge which God has of things, considered not according to their essence, their nature, or their real existence, but under a certain supposition which imports a condition never to be accomplished.

CONDORMIENTES, in church-history, religious sectaries, who hold their name from sleeping all together, men and women, young and old. They arose in the thirteenth century near Cologne, where they are said to have worshipped an image of Lucifer, and to have received answers and oracles from him.

CONDUCTOR, in surgery, an instrument which serves to conduct the knife in the operation of cutting for the stone, and in laying up sinuses and fistulas. See SURGERY.

CONDUCTOR, in electricity. All bodies are divided into conductors and non-conductors. The latter are called electrics. See ELECTRICITY.

CONDUCTORS, in military affairs, are assistants given to the commissary of the stores to receive or deliver out stores to the army, to attend at the magazines by turns when in garrison, and to look after the ammunition-waggons in the field. They bring their accounts every night to the commissary, and are immediately under his command.

CONDYLOMA, in medicine, a tubercle or callous eminence which arises in the folds of the anus, or rather a swelling or hardening of the wrinkles of that part. See SURGERY.

CONE, in geometry, a solid figure, having a circle for its base, and its top terminated in a point or vertex. See CONIC SECTIONS.

CONE AND KEY, accounts and key. A woman at the age of 14 or 15, might take the charge of her house and receive cone and key; so that a woman was held to be of competent years, when she was able to keep the accounts and key of her house.

CONFECTION signifies a liquid or soft electuary, of which there are various sorts directed in dispensatories. See PHARMACY.

CONFECTOR, in Roman antiquity, a sort of gladiator hired to fight in the amphitheatre against beasts. thence also denominated bestiarius.

CONFEDERACY, in law, is when two or more confederate, to do any damage or injury to another, or to commit any unlawful act. And though a writ of confederacy do not lie if the party be not indicted and in a lawful manner acquitted, yet false confederacy between divers persons shall be punished, though nothing be put in execution.

CONFERVA, a genus belonging to the cryptogamia class of plants; and in the natural method ranking under the 57th order, algæ. The tubercles are of different sizes, on capillary, very long fibres. There are 21 species, most of which grow on stones in slow streams, on the sides of cisterns, or in ponds.

CONFESSION of offence, in law, is when a prisoner is appealed or indicted of treason or felony, and brought to the bar to be arraigned, and his indictment being read to him, the court demands what he can say thereto: then either he confesses the offence, and the indictment to be true, or pleads Not Guilty.

Confession is two-fold, either express or implied. An express confession is, when a person directly confesses the crime with which he is charged, which is the highest conviction that can be. 2 Haw. 333. But it is usual for the court, especially if it be out of clergy, to advise the party to plead, and put himself upon his trial, and not immediately to record his confession, but to admit him to plead. 2 H. H. 225. An implied confession is, where a defendant in a case not capital, does not directly own himself guilty, but in a manner admits it, by yielding to the king's mercy, and desiring to submit to a small fine; which submission the court may accept if they think fit, without putting him to a direct confession. 2 Haw. 233.

Confession in a civil action. Sometimes there is a confession in a civil action, but not usually of the whole complaint; for then the defendant would probably end the matter sooner, or not plead at all, but suffer judgment to go by default; but sometimes, after tender and refusal of debt, if the creditor harass his debtor with an action, it then becomes necessary for the defendant to confess the debt and plead the tender; for a tender by the debtor and refusal by the creditor, will in all cases discharge the costs. 4 Black. 303. So in order to strengthen the creditor's security, it is usual for the debtor to execute a warrant of attorney to confess judgment in an action to be brought by such creditor: which judgment when confessed, is complete and binding. 3 Black. 397.

CONFESSION, among divines, the verbal acknowledgment which a Christian makes of his sins.

The Romish church requires confession, not only as a duty, but has advanced it to the dignity of a sacrament: this confession is made to the priest, and is private and auricular; and the priest is not to reveal it under pain of the highest punishment.

CONFESSION *of faith*, a list of the several articles of

belief in any church, as the Augsburg confession is that of the Lutheran church.

CONFESSIONAL, or CONFESSIONARY, a place in churches, under the great altar, where the bodies of deceased saints, martyrs, and confessors, were deposited. This word is also used by the Romanists for a desk in the church where the confessor takes the confessions of the penitents.

CONFIRMATION, in law, is a conveyance of an estate or right in esse, whereby a voidable estate is made sure and unavoidable, or whereby a particular estate is increased. Thus a bishop grants his chancellorship by patent, for the term of the patentee's life; this is no void grant, but voidable by the bishop's death, except it be strengthened by the confirmation of the dean and chapter. 2 Black. 325.

CONFISCATE, in law: if a man be indicted that he feloniously stole the goods of another man, when in truth they are the proper goods of him indicted, and which being brought into court against him he disclains them, by this disclaimer he shall lose the goods, although afterwards he be acquitted of the felony, and the king shall have them as confiscated. Staundf. pl. cor. l. c. 24.

CONFORMATION, in medicine, that make and construction of the human body, which is peculiar to every individual. Hence those diseases called morbi malæ conformations, or organical diseases, are those which depend upon the bad conformation of the parts. Those, if external, may admit of chirurgical cure; and proper exercise, regimen, and medicine, may sometimes contribute much to the relief even of those which are internal, or at least may render them supportable.

CONGE' *d'elire*, in ecclesiastical polity, the king's permission royal to a dean and chapter in the time of a vacancy, to choose a bishop; or to an abbey, or priory, of his own foundation, to choose their abbot or prior. The king of England, as sovereign patron of all archbishoprics, bishoprics, and other ecclesiastical benefices, had of ancient time free appointment to all ecclesiastical dignities, whenever they chanced to be void; investing them first per baculum and annulum, and afterwards by his letters patent; and in course of time he made the election over to others, under certain forms and limitations; as that they should, at every vacation, before they choose, demand the king's congé d'elire, and after the election, crave his royal assent, &c.

CONGE', in architecture, a mould in form of a quarter-round, or a cavetto, which serves to separate two members from one another; such as that which joins the shaft of the column to the cincture, called also apophyge.

CONGES are also rings or ferrels formerly used in the extremities of wooden pillars, to keep them from splitting, afterwards imitated in stone-work.

CONGELATION, freezing, or such a change produced by cold in a fluid body, that it quits its former state and becomes congealed. See COLD, and FREEZING.

CONGIARY, CONGIARIUM, in Roman antiquity, a kind of donative of wine or oil, bestowed on that people by their emperors, and so called from the congius, wherewith it was measured out to them. Sometimes, indeed, the congiary was made in money or corn; and the medals struck on such occasions, are known by the same name.

CONGIUS, a liquid measure of the ancient Romans containing the eighth part of the amphora, or the fourth of the urna, or six sextarii. The congius in English measure contains 207,0676 solid inches; that is, seven pints, 4,942 solid inches.

CONGLOBATE GLAND, in anatomy, a little smooth body, wrapt up in fine skin, by which it is separated from all other parts, only admitting an artery and a nerve to pass in, and giving way to a vein and excretory canal to come out, of which sort are the glands of the brain.

CONGLOMERATE GLAND, that which is composed of several little conglobate glands, all tied up together in one common tunicle or membrane. Sometimes all their excretory ducts unite, and make one common pipe, through which the liquor of them all runs, as the pancreas and parotides do. Sometimes the ducts uniting, form several pipes, which only communicate with one another by cross canals; and such are the mammæ: others again have several pipes without any communication with one another, of which sort are the glandulæ lachrymales and prostatæ: and a fourth sort, is when each little gland has its own excretory duct, through which it transmits its liquor to a common bason; as the kidneys.

CONGLUTINATION, the gluing or fastening any two bodies together by the intromission of a third, whose parts are unctuous and tenacious in the nature of glue.

CONGREGATION, an assembly of several ecclesiastics united, so as to constitute one body; as an assembly of cardinals, in the constitution of the pope's court, met for the despatch of some particular business. These assemblies, being sixteen in number, are distributed into several chambers, after the manner of our offices and courts: the first whereof is the pope's congregation, whose business it is to prepare the most difficult beneficiary matters to be afterwards debated in the consistory: the second is the congregation of the holy office, or the inquisition: the third is the congregation de propaganda fide: the fourth is the congregation for explaining the council of Trent: the fifth is the congregation of the index, deputed to examine into pernicious and heretical books: the sixth is the congregation of immunities, established to obviate the difficulties that arise in the judgments of such suits as are carried on against churchmen: the seventh is the congregation of bishops and regulars: the eighth is the congregation for the examination of bishops, &c.

CONGREGATIONALISTS, in church history, a sect of protestants who reject all church government, except that of a single congregation. In other matters, they agree with the presbyterians.

CONGRESS, in political affairs, an assembly of commissioners, envoys, deputies, &c. from several courts, meeting to concert matters for their common good.

CONIC SECTIONS are curve lines formed by the intersections of a cone and a plane. Before we speak of these sections, we shall briefly describe the cone itself and some of its properties.

A cone may be conceived to be generated in the following manner: Take an immoveable point A (Plate XXXIV. Conic Sections, fig. 1.) elevated above the plane of a circle BCDE; and suppose a straight line XZ drawn through the point and extended both ways from it to an

indefinite length, to be carried quite round the circle, all the while touching its circumference, and continuing still fixed to the immoveable point; the line by this motion will describe two conic surfaces, which are vertical or opposite, having their common vertex at the immoveable point.

The solid contained within this conic surface, between the immoveable point A and the circumference of the circle BCDE, is a cone: the immoveable point A is the vertex; the circle BCDE is the base; and a straight line AF drawn from the vertex to the centre of the base, is the axis of the cone: all straight lines drawn from the vertex to the circumference of the base, as AB, AC, AD, AE, &c. are sides of the cone. If the axis of a cone be perpendicular to its base, it is called a right cone, as in fig. 2.; if the axis be inclined to the base, it is called a scalene or oblique cone, such as that in fig. 3.; and a right cone is always understood, when the contrary is not expressed.

If this leg or axis be greater than half the base, the solid produced is an acute-angled cone; if less, it is an obtuse-angled cone; and if equal, a right-angled cone. Thus the cone BAC (fig. 4.) is less acute than the cone BDC, because the angle BDF is less than the angle BAF.

Properties of the cone. 1. Cone and pyramids having the same bases and altitudes, are equal to each other. It is shown that every triangular prism may be divided into three equal pyramids; and therefore that a triangular pyramid is one-third of a prism standing on the same base, and having the same altitude. Hence, since every multangular body may be resolved into triangular ones, every pyramid is the third part of a prism, standing upon the same base, and having the same altitude; and as a cone may be esteemed an infinite-angular pyramid, and a cylinder an infinite-angular prism, a cone is a third part of a cylinder which has the same base and altitude. Hence we have a method of measuring the solidity and surface of a cone and pyramid. Thus, find the solidity of a prism or cylinder, having the same base with the cone or pyramid; which found, divide by 3, the quotient will be the solidity of the cone or pyramid: or the solidity of any cone is equal to the area of the base multiplied into one third part of its altitude. As for the surface, that of a right cone, not taking in the base, is equal to a triangle whose base is the periphery, and altitude the side of the cone; therefore the surface of a right cone is had by multiplying the periphery of the base into half of the side, and adding the product to that of the base.

2. The altitudes of similar cones are as the radii of the bases; and the axes likewise are as the radii of the bases, and form the same angle with them.

3. Cones are to one another in a ratio compounded of their bases and altitudes.

4. Similar cones are in a triplicate ratio of their homologous sides, and likewise of their altitudes.

5. Of all cones standing upon the same base, and having the same altitude, the superficies of that which is most oblique is the greatest, and so the superficies of the right cone is the least; but the proportion of the superficies of an oblique cone to that of a right one, or which is the same thing, the comparison thereof to a circle, or the conic sections, has not yet been determined.

If a cone be cut by a plane through the vertex, the section will be a triangle ABC, Plate fig. 6.

If a cone be cut by a plane parallel to its base, the section will be a circle. If it be cut by a plane DEF, fig. 6. in such a direction that the side AC of a triangle passing through the vertex, and having its base BC perpendicular to EF, may be parallel to DP, the section is a parabola; if it be cut by a plane DR, fig. 7, meeting AC, the section is an ellipse; and if it be cut by a plane DMO, fig. 8, which would meet AC extended beyond A, it is an hyperbola.

If any line HG, fig. 6, be drawn in a parabola perpendicular to DH, the square of HG will be to the square of EP as DG to DP; for let LHK be a section parallel to the base, and therefore a circle, the rectangle LGK will be equal to the square of HG, and the rectangle BPC equal to the square of EP; therefore these squares will be to each other as their rectangles, that is, as BP to LG, that is, DP to DG.

There are three modes of investigating the properties of these curves. 1. By taking the demonstrations from the sections of a cone, which, from the many intersections of planes with planes, and planes with solids, is apt to perplex the learner, and is now seldom adopted. 2. By taking some general property of the figures on a plane, from which all the rest may be determined geometrically; or by taking the general property of each curve singly, and from thence deducing geometrically all the other properties of that curve. 3. By taking the equation to all the curves, from whence their respective properties may be discovered algebraically; or by taking the equation to each single curve, from whence its properties may be discovered algebraically.

By whichever of these three methods the properties of conic sections are investigated, the general property is discovered, which makes the bases of the other methods. If they are considered as curves on a plane surface, they are shown to have the same properties with those formed by the intersections of a plane with a cone; and again, the equation is produced, which makes the basis of the algebraical process. For a beginner, the geometrical method seems clearly to have the preference; and that which deduces from a common property the relations of each curve to the other, as well as the respective properties of each curve, seems to be better than that which considers each curve separately, and, after an examination of its properties, enters into a comparison of each curve with the others. Boscovich in a very elegant manner has deduced the properties of the three curves, from a property common to all; and his method has been made still easier for beginners lately by Mr. Newton, of Jesus-college, Cambridge; who, laying aside the musical proportion on which Boscovich founds his demonstrations, has, within a short compass, introduced every thing requisite for the study of the Principia and the higher mathematics. The basis of this method is the relation of two lines to each other, drawn the one from a given point, the other perpendicular to a line given in position.

(1) If any point S be assumed without the line DX (fig. 9. 10.), and, whilst the line SP revolves about S as a centre, a point P moves in it in such a manner that its distance from the point S shall always be to PE (its distance from the line DX) in a given ratio, the curve described by the point P is called a conic section, a parabola, an ellipse, or an hyperbola, according as SP is equal to, less,

or greater than, PE. (2) The indefinite right line DX is called the directrix. (3) The point S is called the focus. (4) The ratio of SP to PE is called the determining ratio. (5) If a line SD be drawn through the focus perpendicular to the directrix, which is produced indefinitely, it is called the axis of the conic section. (6) The point A, where the curve meets the axis, is called the vertex. (7) A right line LST, drawn through the focus parallel to the directrix, and terminated by the curve in the points L, T, is called the principal parameter, or the latus rectum.

Cor. 1. SP being greater than PE in the hyperbola, two curves will be described, one on each side of the directrix; which are called opposite hyperbolas.

Cor. 2. When the revolving line SP comes into the position SAD; SP, PE, will be equal to SA, AD; therefore, SA is to AD in the determining ratio.

Cor. 3. When the line SP comes into the position SL or ST, the distance of P from the directrix will be equal to SD, and SL or ST will be to SD in the determining ratio; and therefore the latus rectum LT is bisected in S.

Cor. 4. The latus rectum in the parabola is equal to twice the distance of the focus from the directrix, or to four times its distance from the vertex: for SL is equal to SD, and SA is equal to AD; therefore LT is equal to twice SD, or to four times SA.

(8) The tangents DLQ, DT*q* (figs. 11, 12.), which are drawn through the extremities of the latus rectum, are called focal tangents. (9) The right line AM, in the ellipse and hyperbola, is called the transverse axis, or the axis major. (10) If the transverse axis be bisected in C, the point C is called the centre of the ellipse or hyperbola. (11) If a line B*Cb*, which is bisected in C, be drawn perpendicular to the transverse axis, and CB, C*b*, be each of them a mean proportional between SA, SM, the segments of the axis intercepted between the focus and the vertices B*Cb*, is called the conjugate axis, or the axis minor. (12) A right line PN*p*, drawn through any point N in the axis parallel to the tangent KAG, or perpendicular to the axis, and terminated by the curve in the points P and *p*, is called an ordinate to the axis. (13) And the segment of this axis AN, intercepted between the ordinate and the vertex, in all the sections, as also the other segment NM in the ellipse and hyperbola, is called an abscissa. (14) Any line passing through the centre of an ellipse or hyperbola, which is terminated both ways by the curve in the former, and by the opposite curves in the latter, is called a diameter. (15) A line drawn through any point in the parabola parallel to the axis, is called a diameter to the parabola. (16) Any point where a diameter meets the curve is called a vertex to that diameter. (17) If from the centre C, at the distance CA (fig. 13.) half the transverse axis, a circle be described, cutting the directrix of the hyperbola in the points, H, *h*, and lines be drawn from the centre through the points of intersection, these lines are called the asymptotes. (18) If AM be the transverse axis, and B*b* the conjugate axis, of any two opposite hyperbolas; and two other hyperbolas be described, of which the transverse axis is B*b*, and the conjugate axis AM; these hyperbolas are said to be conjugate to the former. (19) When the two axes are equal, the hyperbolas are said to be equilateral. (20) If a right line be drawn through any point in the diameter of a conic section parallel to the tangent at its vertex, which is terminated both ways by the curve, it is called an ordinate to that diameter. (21) The segments of any diameter of a conic section, which is intercepted between an ordinate and the vertex, is called an abscissa. (22) A diameter which is parallel to the tangent at the vertex of any diameter of the ellipse or hyperbola, is called a conjugate diameter. (23) A line which is a third proportional to any diameter of the ellipse or hyperbola and its conjugates, is called a parameter to that diameter. (24) If a line be drawn through the focus of a parabola, parallel to the ordinates of any diameter, which is terminated both ways by the curve, it is called a parameter to that diameter.

From these fundamental properties all the others are derived, and the curves may be described mechanically. This description depends for the *parabola*, on the property that a line from any point in the curve to the focus is equal to the line drawn from the same point perpendicularly on the directrix; for the *ellipse*, on the property that the sum of the lines drawn from the foci to any point is equal to the major axis; for the *hyperbola*, that the difference of the lines drawn from the foci to any point in the curve is equal to the major axis. Hence to draw the parabola.

Description of conic sections on a plane.

1. Parabola. Let AB (fig. 14.) be any right line, and C any point without it, and DKF a ruler, which let be placed in the same plane in which the right line and point are, in such a manner that one side of it, as DK, be applied to the right line AB, and the other side KF coincide with the point C; and at F, the extremity of the side KF, let be fixed one end of the thread FNC, whose length is equal to KF, and the other extremity of it at the point C; and let part of the thread, as FN, be brought close to the side KF by a small pin N; then let the square DKF be removed from B towards A, so that all the while its side DK be applied close to the line BA; and in the mean time the thread being extended, will always be applied to the side KF, being stopt from going from it by means of the small pin; and by the motion of the small pin N there will be described a certain curve, which is called a semi-parabola. And if the square be brought to its first given position, and in the same manner be moved along the line AB, from B towards H, the other semi-parabola will be described.

2. Ellipse. If any two points, as A and B (fig. 15.), be taken in any plane, and in them are fixed the extremities of a thread, whose length is greater than the distance between the points, and the thread extended by means of a small pin C; and if the pin be moved round from any point until it return to the place from whence it began to move, the thread being extended during the whole time of the revolution, the figure which the small pin by this revolution describes is called an ellipse.

3. Hyperbola. If to the point A (fig. 16.) in any plane, one end of the ruler AB be placed in such a manner, that about that point, as a centre, it may freely move; and if to the other end B of the ruler AB be fixed the extremity of the thread BDC, whose length is less than the ruler AB, and the other end of the thread being fixed in the point C, coinciding with the side of the ruler AB which is in the same plane with the given point A; let part of the thread, as BD, be brought close to the

side of the ruler AB, by means of a small pin D; then let the ruler be moved about the point A, from C towards T, the thread all the while being extended, and the remaining part coinciding with the side of the ruler being stopt from going from it by means of the small pin; and by the motion of the small pin D, a certain figure is described, which is called the semi-hyperbola.

The ellipse returns into itself. The parabola and hyperbola may be extended without limit.

Every line perpendicular to the directrix of a parabola meets it in one point, and falls afterwards within it; and every line drawn from the focus meets it in one point, and falls afterwards without it. And every line that passes through a parabola, not perpendicular to the directrix, will meet it again, but only once.

Every line passing through the centre of an ellipse is bisected by it; the transverse axis is the greatest of all these lines, the lesser axis the least, and those nearer the transverse axis greater than those more remote.

In the hyperbola, every line passing through the centre is bisected by the opposite hyperbola, and the transverse axis is the least of all these lines; also the second axis is the least of all the second diameters. Every line drawn from the centre within the angle contained by the asymptotes, meets at once, and falls afterwards within it; and every line drawn through the centre without the angle, never meets it; and a line which cuts one of the asymptotes, and cuts the other extended beyond the centre, will meet both the opposite hyperbolas in one point.

If a line GM (fig. 14.) be drawn from a point in a parabola perpendicular to the axis, it will be an ordinate to the axis, and its square will be equal to the rectangle under the abscissa MI and latus rectum; for because GMC is a right angle, GM^2 is equal to the difference of GC^2 and CM^2; but GC is equal to GE, which is equal to MB; therefore GM^2 is equal to $BM^2 - CM^2$; which, because CI and IB are equal, is (8 Euc. 2.) equal to four times the rectangle MI and IB, or equal to the rectangle under MI and the latus rectum.

Hence it follows, that if different ordinates be drawn to the axis, their squares, being each equal to the rectangle under the abscissa and latus rectum, will be to each other in the proportion of the abscissas; which is the same property as takes place in the parabola cut from the cone, and proves those curves to be the same.

This property is extended also to the ordinates of other diameters, whose squares are equal to the rectangle under the abscissas and parameters of their respective diameters.

In the ellipse, the square of the ordinate is to the rectangle under the segments of the diameter, as the square of the diameter parallel to the ordinate is to the square of the diameter to which it is drawn, or as the first diameter to its latus rectum; that is, LK^2 (fig. 15.) is to $EK \times KF$ as EF^2 to GH^2.

In the hyperbola, (fig. 16.) the square of the ordinate is to the rectangle contained under the segments of the diameters betwixt its vertices, as the square of the diameter parallel to the ordinate, to the square of the diameter to which it is drawn, or as the first diameter to its latus rectum; that is, SX^2 is to $EX \times XK$ as MN^2 to KE^2.

Or if an ordinate be drawn to a second diameter, its square will be to the sum of the squares of the second diameter, and of the line intercepted betwixt the ordinate and centre, in the same proportion; that is, RS^2 (fig. 16.) is to ZG^2 added to GM^2 as KE^2 to MN^2.

These are the most important properties of the conic sections; and by means of these, it is demonstrated, that the figures are the same described on a plane as cut with a cone; which we have demonstrated in the case of the parabola.

From the genesis of the sections it may be observed how one section degenerates into another. For an ellipsis being that plane of any section of the cone which is between the circle and parabola, it will be easy to conceive that there may be a great variety of ellipses produced from the same cone; and when the section comes to be exactly parallel to one side of the cone, then the ellipsis degenerates into a parabola. Now a parabola being that section whose plane is always parallel to the side of the cone, cannot vary as the ellipsis may; for as soon as it begins to move out of that position of being parallel to the side of the cone, it degenerates either into an ellipsis or hyperbola: that is, if the section inclines towards the plane of the cone's base, it becomes an ellipsis; but if it incline towards the cone's vertex, it then becomes an hyperbola, which is the plane of any section that falls between the parabola and the triangle; and therefore there may be as many varieties of hyperbola produced from one and the same cone as there may be ellipses.

In short, a circle may change into an ellipsis, the ellipsis into a parabola, the parabola into an hyperbola, and the hyperbola into a plain isosceles triangle. And the centre of the circle, which is its focus, divides itself into two focuses, as soon as the circle begins to degenerate into an ellipsis; but when the ellipsis changes into a parabola, one end of its foci vanishes, and the remaining focus goes along with the parabola when it degenerates into an hyperbola. And when the hyperbola degenerates into a plain isosceles triangle, this focus becomes the vertical point of the triangle, namely, the vertex of the cone. So that the centre of the cone's base may be truly said to pass gradually through all the sections until it arrives at the vertex of the cone, still carrying its latus rectum along with it. For the diameter of a circle being that right line which passes through its centre or focus, and by which all other right lines drawn within the circle are regulated and valued, may be called the circle's latus rectum; and though it lose the name of diameter when the circle degenerates into an ellipsis, yet it retains the name of latus rectum with its first properties in all the sections, gradually shortening as the focus carries it along from one section to another, until at last both it and the focus become coincident, and terminate in the vertex of the cone.

Equations of the conic sections are derived from the above properties. The equation of any curve is an algebraic expression, which denotes the relation betwixt the ordinate and abscissa; the abscissa being equal to x, and the ordinate equal to y.

If p be the parameter of a parabola, then $y^2 = px$; which is an equation for all parabolas.

If a be the transverse diameter of any ellipses, p its parameter; then $y^2 = \frac{p}{a}(ax - x^2)$, an equation for an ellipses.

If a be a transverse diameter of a hyperbola, p its parameter; then $y^2 = \frac{p}{a} \times \overline{ax + x^2}$.

If a be a second diameter of a hyperbola, then $y^2 = \frac{p}{a} \times \overline{a^2 + x^2}$; which are equations for all hyperbolas.

As all these equations are expressed by the second powers of x and y, all conic sections are curves of the second order; and conversely, the locus of every quadratic equation is a conic section, and is a parabola, ellipse, or hyperbola, according as the form of the equation corresponds with the above ones, or with some other deduced from lines drawn in a different manner with respect to the section.

General properties of conic sections.—A tangent to a parabola bisects the angle contained by the lines drawn to the focus and directrix; in an ellipse and hyperbola, it bisects the angle contained by the lines drawn to the foci.

In all the sections, lines parallel to the tangent are ordinates to the diameter passing through the point of contact; and in the ellipse and hyperbola, the diameters parallel to the tangent, and those passing through the points of contact, are mutually conjugate to each other. If an ordinate be drawn from a point to a diameter, and a tangent from the same point which meets the diameter produced; in the parabola, the part of the diameter betwixt the ordinate and tangent will be bisected in the vertex; and in the ellipse and hyperbola, the semidiameter will be a mean proportional between the segments of the diameter, betwixt the centre and ordinate, and betwixt the centre and tangent.

The parallelograms formed by tangents drawn through the vertices of any conjugate diameters, in the same ellipse or hyperbola, will be equal to each other.

Properties peculiar to the hyperbola.—As the hyperbola has some curious properties arising from its asymptotes which appear at first view almost incredible, we shall briefly demonstrate them.

(1) The hyperbola and its asymptotes never meet: if not, let them meet in S (fig. 16.); then by the property of the curve KX × XE is to SX² as GE² to GM² or EP²; that is, as GX² to SX²; wherefore KX × XE will be equal to the square of GX; but KX × XE, together with the square of GE, is also equal to the square of GX; which is absurd.

(2) If a line be drawn through an hyperbola parallel to its second axis, the rectangle contained by the segments of that line, betwixt the point in the hyperbola and the asymptotes, will be equal to the square of the second axis.

For if SZ (fig. 16.) be drawn perpendicular to the second axis, by the property of the curve MG², that is, PE², is to GE², as the squares ZG and the square of MG together, to SZ² or GX²; but RX² and GX² are in the same proportion, because the triangles RXG, PEG, are equiangular; therefore the square ZG and MG are equal to RX², from which, taking the equal squares of SX and ZG, there remains the rectangle RSV, equal MG².

(3) Hence, if right lines be drawn parallel to the second axis, cutting an hyperbola and its asymptotes, the rectangles contained betwixt the hyperbola and points where the lines cut the asymptotes will be equal to each other; for they are severally equal to the square of the second axis.

(4) If from any points, d and S, in an hyperbola, there be drawn lines parallel to the asymptotes $d\ a$ SQ and S $b\ d\ c$, the rectangle under $d\ a$ and $d\ c$ will be equal to the rectangle under QS and S b; also the parallelograms $d\ a$ G c, and SQG b, which are equiangular, and consequently proportional to the rectangles, are equal.

For draw YW RV parallel to the second axis, the rectangle Y $d \times d$ W is equal to the rectangle RS × SW: wherefore WD is to SV as RS is to d Y. But because the triangles RQS, a YD, and GSV, $c\ d$ W, are equiangular, W d is to SV as $c\ d$ to S b, and RS is to DY as SQ to $d\ a$; wherefore, $d\ c$ is to S b as SQ to $d\ a$; and the rectangle $d\ c$, $d\ a$, is equal to the rectangle QS, S b.

(5) The asymptotes always approach nearer the hyperbola.

For, because the rectangle under SQ and S b or QG, is equal to the rectangle under $d\ a$ and $d\ c$, or AC and QG is greater than a G; therefore, $d\ a$ is greater than QS.

(6) The asymptotes come nearer the hyperbola than any assignable distance.

Let X be any small line. Take any point, as d in the hyperbola, and draw $d\ a$, $d\ c$, parallel to the asymptotes: and as X is to $d\ a$, so let a G be to GQ. Draw QS parallel to $a\ d$, meeting the hyperbola in S; then QS will be equal to X. For the rectangle SQ × QG will be equal to the rectangle $d\ a \times a$ G; and consequently SQ is to $d\ a$ as AG to GQ.

If any point be taken in the asymptote below Q, it can easily be shown that its distance is less than the line X.

Uses of conic sections.—Any body, projected from the surface of the earth, describes a parabola, to which the direction wherein it is projected is a tangent: and the distance of the directrix is equal to the height from which a body must fall to acquire the velocity with which it is projected: hence the properties of the parabola are the foundation of gunnery.

All bodies acted on by a central force which decreases as the square of the distances increases, and impressed with any projectile motion making any angle with the direction of the central force, must describe parabolas, ellipses, and hyperbolas, according to the proportion between the central and projectile force. This is proved by direct demonstration.

The great principle of gravitation acts in this manner: and all the heavenly bodies describe conic sections, having the sun in one of the foci; the orbits of the planets are ellipses, whose transverse and lesser diameters are nearly equal. It is uncertain whether some of the comets describe ellipses with very unequal axes, and so return after a great number of years; or whether they describe parabolas and hyperbolas, in which case they will never return.

They are of great use also in many other parts of the mathematics; in dialing, for delineating the signs in the projection of the sphere, many of whose circles are projected into the curves; in optics, to reflect or refract rays accurately to a focus; in logarithms, and in the higher parts of algebra, one or other of them is continually ap-

plied; and no one can make any great progress in the mathematics, without understanding thoroughly the chief properties of conic sections.

The principal writers on conic sections in modern days are, Hamilton, Robertson, Vince, Newton, Simson and Hutton.

CONJUGATE *diameter*, or axis of an ellipsis, the shortest of the two diameters, or that bisecting the transverse axis.

Conjugate *hyperbolas*. See Conic Sections.

CONJUGATION, in grammar, a regular distribution of the several inflections of verbs in their different voices, moods, tenses, numbers, and persons, so as to distinguish them from one another.

The Latins have four conjugations, distinguished by thet erminations of the infinitive āre ēre, ere, and īre; the vowels before *re* of the infinitive in the first, second, and fourth conjugations, being long vowels, and that before *re* in the infinitive of the third being a short one. See Vowel.

The English have scarcely any natural inflexions, deriving all their variations from additional particles, pronouns, &c. whence there is scarcely any such thing as strict conjugation in that language.

CONIUM, *hemlock*, a genus of the digynia order, in the pentandria class of plants, and in the natural method ranking under the 45th order, umbellatæ. The partial involucra are halved, and most triphyllous: the fruit subglobose and quinque-striated, the striæ crenated on each side. There are five species; the most remarkable are:

1. Conium Africanum, with prickly seeds, a native of the Cape of Good Hope, and rarely growing above nine inches high: the lower leaves are divided like those of the small wild rue, and are of a greyish colour; those upon the stalk are narrow, but of the same colour: these are terminated by umbels of white flowers, each of the larger umbels being composed of three small ones; the involucrum has three narrow leaves situated under the umbel.

2. Conium maculatum, or the greater hemlock, grows naturally on the sides of banks and roads in many parts of America. It is a biennial plant, which perishes after it has ripened its seeds. It has a long taper root like a parsnip, but smaller. The stalk is smooth, spotted with purple; and rises from four to upwards of six feet high, branching out towards the top, with decompounded leaves. The stalks are terminated by umbels of white flowers. This species is sometimes applied externally in the form of decoction, infusion, or poultice, as a discutient. These are apt to excoriate, and their vapour is to some particularly disagreeable and hurtful. The stalks are insignificant, and the roots very virulent. With regard to its virtue, when taken internally, it has been generally accounted poisonous; which it doubtless is, in a high degree, when used in any considerable quantity. But Dr. Stoerk has lately found, that in certain small doses it may be taken with great safety; and that, without disordering the constitution, it sometimes proves a powerful resolvent in obstinate disorders. In scirrhus, the internal and external use of hemlock has been found useful, but mercury has been generally used at the same time. In open cancer, it often abates the pains, and is free from the constipating effects of opium. It is likewise used in scrophulous tumours and ulcers in general. It is also recommended by some in chin-cough and other diseases. Its common and perhaps best form is that of the powdered leaves, in the dose at first of two or three grains a day, which in some cases has been gradually increased to upwards of two ounces without producing giddiness. An extract from the seeds is said to produce giddiness sooner than that from the leaves. Hence, while both the London and Edinburgh colleges have given a place to the *succus spissatus cicutæ*, into the pharmacopœia of the latter an *extractum seminum cicutæ* is also introduced.

3. Conium tenuifolium, with striated seeds, differs from the last in having taller stalks, which are not so much spotted. The leaves are much narrower, and of a paler green; and this difference is constant. It is a biennial plant, and grows naturally in Germany.

CONJUNCTION, in astronomy, the meeting of two stars or planets in the same degree of the zodiac.

Conjunction, in grammar, an indeclinable word or particle, which serves to join words and sentences together, and thereby shows their relation or dependence one upon another.

CONJURATION. To use conjuration, witchcraft, &c. was made felony by the 1st Jac. I. c. 12.; but that superstitious statute having produced many pernicious effects, it was wisely repealed by the 9th Geo. II. c. 5., wherein it is enacted, that no prosecution, suit, or proceeding, shall be commenced or carried on against any person for witchcraft, sorcery, enchantment, or conjuration, or for charging another with any such offence, in any court whatsoever. But, by the same statute, if any person shall pretend to exercise or use any kind of witchcraft, sorcery, enchantment, or conjuration, or undertake to tell fortunes, or pretend from his skill or knowledge in any occult or crafty science to discover where or in what manner any goods or chattels supposed to have been stolen or lost may be found; every person so offending, being convicted on indictment or information, shall suffer imprisonment for a year without bail or mainprize; and once in each quarter of the year, in some market-town of the proper county upon the market-day there, stand openly on the pillory for one hour; and shall also (if the court by which such judgment shall be given shall think fit) be obliged to give sureties for his good behaviour, in such sum and for such time as the court shall judge proper, according to the circumstances of the offence; and in such case shall be further imprisoned till such sureties shall be given. 4 Black. 60.

CONNARUS, Ceylon sumach, a genus of the decandria order in the monadelphia class of plants, and in the natural method ranking with those of which the order is doubtful. The stigma is simple; the capsule bivalved, unilocular, and monospermous. There are four species; the most remarkable is:

Connarus monocarpus, a native of India. It rises with a ligneous stalk eight or ten feet high, which is hard, rigid, and covered with a black bark; and divides upwards into two or three branches with trifoliate leaves, having long footstalks placed alternate. It is propagated by cuttings, and is treated like other tender exotics.

CONNIVENT *valves*, in anatomy, those wrinkles,

cellules, and vascules, which are found in the inside of the two great intestines, the ileum and jejunum.

CONOID, in geometry, a solid body, generated by the revolution of a conic section about its axis. See Conic Sections.

Conoid, *elliptical*, is a solid formed by the revolution of an ellipsis about one of its diameters, and more generally called a spheroid.

Conoid, *parabolical*, is generated by the revolution of a parabola about its axis.

CONOID, *hyperbolical*, is generated by the revolution of an hyperbola about its axis.

CONOIDES, in anatomy, a gland found in the third ventricle of the brain, called pinealis from its resemblance to a pine-apple. Descartes fixed the seat of the rational soul in this gland.

CONOPS, in zoology, a genus of insects belonging to the order diptera; the characters of which are: the rostrum is porrected and joined like a knee; the antennæ terminate by a flat and solid articulation, resembling the bowl of a spoon, with a lateral bristle, which, when closely examined, appears to be very hairy. Of this genus there are thirteen species.

1. The calcitrans is to be found every where, especially in autumn, when it harrasses the horses, and draws blood from them with its sting.

2. The macrocephala might at first sight be mistaken for a species of wasp. It is smooth: the forepart of the head is lemon-colour, as are the poisers; the feet are dun-coloured; the thorax is variegated with black and reddish dun: the same takes place with respect to the segments of the abdomen, some of which are edged with lemon-colour, chiefly the second and part of the third towards the sides: the wings are brown, watered, and clouded. This beautiful conops is found in medows. The eleven other species are not deserving particular notice.

CONOPLEA, in botany, a genus of the cryptogamia class, order fungi; there are but one species known.

CONSANGUINITY, or kindred, is the connection or relation of persons descended from the same stock or common ancestor; and is either lineal or collateral. Lineal consanguinity is that which subsists between persons, of whom one is descended in a direct line from the other; as grandfather, father, and son. Collateral consanguinity is that which subsists between persons descended from the same common ancestor, but not from one another; as brothers, uncles, and nephews. 2 Black. 204.

Consanguinity terminates in the sixth and seventh degree, except in the succession of the crown, in which case it is continued to infinity. Marriage is prohibited by the church to the fourth degree of consanguinity inclusive; but by the law of nature, consanguinity is no obstacle to marriage, except in the direct line.

The civilians call *fratres consanguine*, those born of the same father, in opposition to *fratres uterini*, who are only born of the same mother. It is the common opinion that the former was not allowed to complain of an inofficious testament, that is, of being disinherited without cause, except from the turpitude of the person appointed heir in their place.

CONSCRIPT, *conscriptus*, in Roman antiquity, an appellation given to the senators of Rome, who were called conscript fathers on account of their names being entered all in one register.

CONSECRATION, among medalists, is the ceremony of the apotheosis of an emperor. The consecration on medals is represented thus: on one side is the emperor's head, crowned with laurel, and sometimes veiled, and the inscription gives him the title DIVVS; on the reverse is a temple or altar, or an eagle taking flight toward heaven; and sometimes the emperor is seen in the air, borne up by the eagle; the inscription always CONSECRATIO.

CONSEQUENT *of a ratio*, in mathematics, the latter of the two terms of a ratio, or that to which the antecedent is compared; thus in $m : n$, or m to n, n is the consequent, and m the antecedent. See Ratio, and Proportion.

CONSEQUENTIAL *losses* or *damages*, in law. It is a fundamental principal of law and reason, that he who does the first wrong, shall answer for all the consequential damages. 12 Mod. 639. But this admits of limitation. Though a man do a lawful thing, yet, if any damage thereby befal another, he shall answer if he could have avoided it.

CONSERVATOR, an officer ordained for the security and preservation of the privileges of some cities and communities, having a commission to judge of and determine the differences among them.

In most catholic universities there are two conservators; one of whom decides the differences between the regents, students, &c. and the other takes cognizance of spiritual matters between ecclesiastics: the former is called conservator of royal privileges, or those granted by kings; the latter is called the conservator of apostolical privileges, or those granted by the pope.

Conservator *of the peace*, in our ancient customs, a person who had a special charge to keep the king's peace. The chamberlain of Chester is still a conservator in that county; and petty constables are, by the common law, conservators, &c. of the king's peace.

Conservator *of the truce and safe-conducts*, an officer formerly appointed by the king's letters patent, whose business it was to make inquiry of all offences committed against the king's truce and safe-conducts upon the main seas out of the liberties of the cinque-ports.

CONSERVATORIOS are musical schools established for the instruction of children in music. There are four of these at Venice, designed for the education of girls, and three at Naples for the instruction of boys.

CONSIDERATION, is the material cause of a contract, without which it would not be effectual or binding. Consideration in contracts, is something given in exchange, something that is mutual and reciprocal: as money given for goods sold, or work performed for wages: and a consideration of some sort or other is so absolutely necessary to the forming of a contract, that a *nudum pactum*, or agreement to do or pay any thing on one side without any compensation on the other, is totally void in law; and a man cannot be compelled to perform it. 2 Black. 445. A consideration is necessary to create a debt, otherwise it is a *nudum pactum*. Jenk. 290. in Pl. 27.

CONSIGNMENT, the sending, or delivering over, goods, money, or other property, to another person. It

may be either consigned unconditionally, or for some particular purpose. Consigned goods are supposed in general to be the property of him *by* whom they are consigned, but to be at the disposal of him *to* whom they are consigned.

CONSILUM, in law, is used to signify a speedy day appointed to argue a demurrer; which the court grants after the demurrer joined, on reading the records of the cause.

CONSISTENTES, in church history, an appellation given to such penitents as were permitted to assist at prayers, but not to partake of the sacrament.

CONSISTORY, at Rome, is an ecclesiastical assembly held in the presence of the pope, for the reception of princes or their ambassadors, for the canonization of saints, for the promotion of cardinals, and other important affairs.

When a public consistory is to be held, the pope's throne is erected in the great hall of the apostolic palace: the pope is seated on cloth of gold, under a canopy of the same, and the foot of the throne is covered with red cloth. The cardinal bishops and priests sit on the right, below the throne, and the deacons on the left, but so as to have their faces towards the pope. The archbishops, bishops, prothonotaries, and other prelates, sit on the steps of the throne: on the lowest step the subdeacons, auditors, clerks of the chamber, and acolyths with woollen cowls; and the ecclesiastical officers of the pope's court on the ground. The nephews of the reigning pope, and other Roman princes, are ranged on each side of the throne; and the entrance of the passage leading to the throne is occupied by the pope's guard. Besides the public consistory, there is also a private one, held in a retired chamber, called the chamber of papegay, into which none are admitted but cardinals: here the pope appears in a white silk cassock, and a red vellet cap laced with silver; and here are first proposed and passed all bulls for bishoprics, abbeys, &c. which are thence called consistorial benefices.

In England, the archishop and bishop of every diocese has a consistory court, held before his chancellor or commissary in his cathedral church, or other convenient place in his diocese, for ecclesiastical causes. From the bishop's court the appeal is to the archbishop; from the archbishop's court to the delegates.

CONSOLE, in architecture, an ornament cut upon the key of an arch, which has a projecture, and, on occasion, serves to support little cornices, figures, busts, and vases.

CONSOLIDATION, in the civil law, signifies the uniting the possession or profit of land with the property, and vise versa. Thus, if a man has by legacy usufructum fundi, and afterwards buys the property or fee simple of the heir, this is called a consolidation.

Consolidation, in our law, is the uniting two benefices into one by assent of the ordinary, patron, and incumbent.

CONSONANCE, in music, if we are to deduce the definition of the word from its etymology, is the effect of two or more sounds heard at the same time; but its general signification is confined to concording intervals. When the interval of a consonance is invariable, it is called perfect; and when it may be either major or minor, it is termed imperfect.

CONSONANT, a letter that cannot be sounded without some single or double vowel before or after it. Consonants are first divided into single and double; the double are *x* and *z*, the rest are all single: and these are again divided into mutes and liquids; eleven mutes, *b, c, d, f, v, g, j, k, p, q, t;* and four liquids, *l, m, n, r.* But the most natural division of consonants is that of the Hebrew grammarians, who have been imitated by the grammarians of other oriental languages. These divide the consonants into five classes, with regard to the five principal organs of the voice; which all contribute, it is true, but one more notably than the rest, to certain modifications, which make five general kinds of consonants. Each class comprehends several consonants, which result from the different degrees of the same modification, or from the different motions of the same organs: these organs are the throat, palate, tongue, teeth, lips; whence the five classes of consonants are denominated guttural, palatal, lingual, dental, and labial.

CONSPIRACY, in law, the unlawful confederation of any persons by oath or other covenant, that each of them shall aid and bear the other falsely and maliciously to indict or cause to be indicted, or falsely to move or maintain pleas. From which it seems clearly to follow, that not only those who actually cause an innocent man to be indicted, and also to be tried upon the indictment (whereupon he is lawfully acquitted), are properly conspirators; but that those also are guilty of this offence who basely conspire to indict a man falsely and maliciously, whether they do any act in prosecution of such confederacy or not. 1 Haw. 189. For this offence the conspirators (for there must be at least two to form a conspiracy) may be indicted at the suit of the king, and may be sentenced to fine, imprisonment, and pillory. 4 Black. 136.

CONSTABLE. Lord high constable, an ancient officer of the crown both of England and France, whose authority was so very extensive, that the office has been laid aside in both kingdoms, except upon particular occasions, such as the king's coronation. The constable of France had his person privileged, and during the king's minority was named next to the princes of the blood. The army obeyed him next the king. He managed all that belonged to war, either for punishment of delinquents, distribution of booty, surrender of places, &c. The jurisdiction and functions of this office were afterwards in the mareschals of France. The function of the constable of England consisted in the care of the common peace of the land, in deeds of arms, and matter of war. By a law of Richard II. the constable of England had the determination of things concerning wars and blazonry of arms, which could not be discussed by the common law. The first constable was created by the Conqueror: the office continued hereditary till the 13th of Henry VIII.; when it was laid aside, as being so powerful as to become troublesome to the king.

Constable: by the laws of Alfred, the freemen were to distribute themselves into decemaries and hundreds; and every ten freeholders chose an annual officer, whom they called constable, borsholder, tithingman, or headborough, as the head of the decennary or ten. These in every hundred where there was a feudal lord, were sworn in and admitted by the lord of his steward, in his leet; but where there was no feudal lord, the sheriff, in his

turn, had the swearing of them in. So if there was no feudal lord of the hundred, an annual officer was chosen, who was to preside over the whole hundred, and was called the high constable.

CONSTAT, in law, a certificate that the clerk of the pipe and auditors of the exchequer grant at the request of any person who intends to plead or move in that court, for the discharge of any thing. A constat is superior to an ordinary certificate, because it contains nothing but what is evident on record.

CONSTELLATION, in astronomy, a system of several stars that are seen in the heavens near to one another. Astronomers not only mark out the stars, but, that they may better bring them into order, they distinguish them by their situation and position in respect to each other; and therefore they distribute them into asterisms, or constellations, allowing several stars to make up one constellation; and for the better distinguishing and observing them, they reduce the constellations to the forms of animals, as men, bulls, bears, &c. or to the images of some things known, as of a crown, a harp, a balance, &c. or give them the names of those whose memories, in consideration of some notable exploit, they had a mind to stransmit to future ages. The division of the stars by images and figures is of great antiquity, and seems to be as old as astronomy itself: for in the ancient book of Job, Orion, Arcturus, and the Pleiades, are mentioned: and we meet with the names of many of the constellations in the writings of the first poets, Homer and Hesiod. See ASTRONOMY.

The ancients, in their division of the firmament, took in only so much as came under their notice, distributing it into forty-eight. Modern astronomers divide the whole starry firmament into three regions: 1. The zodiac, or that portion of the heavens in which the planets would appear to move, to an eye placed in the sun. The breadth of this space depends on the inclination of the orbits in which the planets move, to one another; and includes twelve constellations, commonly called the signs of the zodiac, viz. aries, taurius, gemini, cancer, leo, virgo, libra, scorpio, sagittarius, capricornus, aquarius, and pisces. 2. All that region of the heavens that lies on the north side of the zodiac, which contains 21 constellations, viz. the ursa minor and major, draco, cepheus, bootes, corona septentrionalis, hercules, lyra, cygnus, cassiopeia, perseus, andromeda, triangulum, auriga, pegasus, equuleus, delphinus, sagitta, aquila, serpentarius, and serpens; to which were added afterwards two others, viz. that of antinous, which was made of the stars not included in any image, near the eagle; and Berenice's hair, consisting of stars which are near the lion's tail. 3. That region on the southern side of the zodiac, which contains 15 constellations, known to the ancients, viz. cetus, the eridanus, lepus, orion, canis major, canis minor, argo, hydra, crater, corvus, centaurus, lupus, ara, corona meridionalis, and piscis australis: to these are lately added twelve more constellations, which are not to be seen by those who inhabit the northern regions, because of the convexity of the earth, but in the southern parts they are very conspicuous; these are the phœnix, grus, pavo, indus, avis paradisi, triangulum australe, musca, chameleon, piscis volans, toucan, hydrus, xiphias. The galaxy, or milky-way, is also to be reckoned among the constellations. See each constellation, and the number of stars it contains, under its proper head; and also the article ASTRONOMY.

CONSTITUTION, an ordinance, decision, regulation, or law, made by authority of any superior, ecclesiastical or civil. The constitutions of the Roman emperors make a part of the civil law, and the constitutions of the church make a part of the canon law.

CONSTITUTION, by way of eminence, is an appellation given to that bull of pope Clement XI. which begins with the word unigenitus.

CONSTITUTION, *apostolical*, a collection of regulations attributed to the apostles, and supposed to have been collected by St. Clement, whose name likewise they bear. It is the general opinion, however, that they are spurious, and that St. Clement had no concern in them. They appeared first in the 4th age, but have been much changed and corrupted since that time. They are divided into eight books, consisting of a great number of rules and precepts, relating to the duties of Christians, and particularly the ceremonies and discipline of the church. Mr. Whiston, in opposition to the general opinion, asserts them to be a part of the sacred writings dictated by the apostles in their meetings, and written down from their own mouths by St. Clement; and intended as a supplement to the New Testament, or rather as a system of christian faith and polity. The reason why the constitutions are suspected by the orthodox, and perhaps the reason also why their genuineness is defended by Mr. Whiston, is, that they seem to favour Arianism.

CONSTITUTION, in a physical sense, is that particular disposition of the human body, which results from the properties and mutual actions of the solids and fluids, and which renders them capable of exercising the functions proper and conformable to nature.

CONSTRUCTION, in geometry, is the drawing such lines, such a figure, &c. as are previously necessary for the making any demonstration appear more plain and undeniable.

CONSTRUCTION *of equations*, in algebra, is the finding the roots or unknown quantities of an equation, by geometrical construction of right lines or curves; or the reducing given equations into geometrical figures. And this is effected by lines or curves, according to the order or rank of the equation.

The roots of any equation may be determined, that is, the equation may be constructed, by the intersections of a straight line with another line or curve of the same dimensions as the equation to be constructed; for the roots of the equation are the ordinates of the curve at the points of intersection with the right line, and it is well known that a curve may be cut by a right line in as many points as its dimensions amount to. Thus, then, a simple equation will be constructed by the intersection of one right line with another; a quadratic equation, or an effected equation of the 2d rank, by the intersection of a right line with a circle, or any of the conic sections; which are all lines of the 2d order, and which may be cut by the right line in two points, thereby giving the two roots of the quadratic equation. A cubic equation may be constructed by the intersection of the right line with a line of the 3d order, and so on.

But if, instead of the right line, some other line of a

higher order be used, then the second line, whose intersections with the former are to determine the roots of the equation, may be taken as many dimensions lower as the former is taken higher. And in general an equation of any height will be constructed by the intersections of two lines whose dimensions, multiplied together, produce the dimension of the given equation. Thus, the intersections of a circle with the conic sections, or of these with each other, will construct the biquadratic equations, or those of the fourth power; and the intersections of the circle or conic sections with a line of the third order, will construct the equations of the fifth and sixth powers, and so on. For example:

To construct a simple equation. This is done by resolving the given simple equation into a proportion, or finding a third or fourth proportional, &c. Thus 1. If the equation be $ax=bc$; then $a : b :: c : x = \frac{bc}{a}$, the fourth proportional to a, b, c.

2. If $ax = b^2$; then $a : b :: b : x = \frac{b^2}{a}$, a third proportional to a and b.

3. If $ax = b^2 - c^2$; then, since $b^2 - c^2 = \overline{b+c} \times \overline{b-c}$, it will be $a : b+c :: b-c : x = \frac{b+c \times b-c}{a}$, a fourth proportional to a, $b+c$, and $b-c$.

4. If $ax = b^2 \times c^2$; then construct the right-angled triangle ABC, (See Plate XXXIX. Miscel. fig. 17.) whose base is b, and perpendicular is c, so shall the square of the hypothenuse be b^2+c^2, which call h^2; then the equation is $a\,x = h^2$, and $x = \frac{h^2}{a^2}$, a third proportional to a and h.

To construct a quadratic equation. 1. If it be a simple quadratic, it may be reduced to this form $x^2 = a\,b$; and hence $a : x :: x : b$, or $x = \sqrt{a\,b}$ a mean proportional between a and b. Therefore upon a straight line (fig. 18) take $AB = a$; and $BC = b$; then upon the diameter A C describe a semicircle, and raise the perpendicular BD to meet it in D; so shall BD be $= x$ the mean proportional sought between AB and BC, or between a and b.
